Key words: WFDSC-domain-containing protein; antimicrobial protein (AMP); haemocytes; ovary; eyestalk peduncle; tissue repair
Abstract

Crustins are whey acidic four-disulphide core (WFDS C) domain-containing proteins in decapods that are widely regarded as antimicrobial agents that contribute to host defence. Whilst there have been many analyses of crustin gene expression in tissues, few studies have been made of the distribution of the natural proteins. Here we report an immunostaining investigation of carcinin, a native crustin from Carcinus maenas, in the body organs. The results show that the protein is largely confined to the haemocytes with only a weak signal detected in the heart, hepatopanreas and midgut caecum where it is restricted to the outer surfaces. Importantly, carcinin was seen to be deposited by the haemocytes on these surfaces. Higher levels of staining were detected in the gonads with carcinin particularly abundant in the capsule of ovary as well as some oocytes. Conspicuous staining was further evident in the cuticle of the eyestalk peduncles. Ablation of the eyestalks resulted in a reduction of carcinin in the maturing ovary with the mature eggs rarely displaying a strong signal for the protein. Interestingly, the degree of carcinin also strongly increased in the healing peduncle, indicating that the protein may be associated with wounding, cell damage and/or tissue regeneration.

Highlights

- Carcinin protein is mainly present within granulated haemocytes, gonads and eyestalks
- Outer surfaces of other tissues receive carcinin through deposition by haemocytes
- The presence of carcinin in ovaries changes markedly during oocyte maturation
- Carcinin levels increase significantly in damaged and regenerating tissues
1. Introduction

Antimicrobial proteins (AMPs) occur widely across many animal taxa and are generally considered to play key roles in the innate defences because of their ability to kill or inhibit the growth of bacteria, yeasts and/or fungi. AMPs are particularly important in invertebrates as these animals lack specific antibodies and clonally derived lymphocytes as immune effectors, and so rely heavily on innate immune responses for protection against potential infectious agents. The most studied invertebrate AMPs tend to be those from species of economic or environmental significance, especially decapods and molluscs, as well as antibacterial proteins from species that have value as experimental laboratory models (e.g. insects).

In decapods, one of the most commercially important aquatic invertebrate groups, the dominant taxon-specific AMP families are the crustins and penaeidins. Of these two groups, crustins are the most dominant as they occur widely across the Malacostraca, whereas penaeidins are confined to shrimp and prawn (Smith et al., 2010; Smith and Dyrynda, 2015; Destoumiuex-Garzón et al., 2016). In addition to the 50 or so crustins already documented for the Decapoda, crustin-like gene sequences occur more widely across the Pancrustacea, specifically in amphipods, copepods (Smith et al., 2008) and ants (Zhang and Zhu, 2012). Thus these are a noteworthy collection of invertebrate defence proteins and are, accordingly, attracting much research interest.

Crustins are defined as secreted cysteine-rich cationic AMPs of ca 7-14 kDa that have at least one whey acidic four disulphide core (WFDSC) domain at the carboxyl terminus (Smith et al., 2008). Three main types of crustins ((I-III) were originally identified by Smith et al. (2008) based on the number of cys-rich domains (including one WFDSC domain) and the presence, or not, of a glycine-rich domain with 5-8 conserved VGGGLG motifs. However, a fourth type, with a double WFDSC domain, has now also been described (Li et al., 2012) and added to the crustin repertoire.

Certainly, many recent studies of crustins have been directed at mapping the expression of encoding genes in different tissues and quantifying expression changes following various experimental challenges (see review by Smith and Dyrynda, 2015). The reports of these analyses indicate that crustins are mainly expressed in...
haemocytes but appear to be produced also in a variety of other tissues, especially
gills, gut, hepatopancreas and haematopoietic tissue (see review by Smith and
Dyrynda, 2015). However, whilst gene expression levels in these tissues may change
after injection of bacteria, fungi, virus or immune-stimulating compounds, no
consistent pattern of response emerges (Smith and Dyrynda, 2015). Clearly what is
needed is, first, clarification of the localisation of the mature natural protein(s) in the
haemocytes and body organs, and, second, an understanding of where and when
crustins are secreted after infection challenge. Such studies are warranted to provide
a deeper understanding of where and how proteins exert their effect (Pandey and
Mann, 2000). The present study was aimed at addressing the first issue: namely
tissue localisation of crustin in vivo.

The crab, Carcinus maenas, was chosen as the experimental animal because its size
and tolerance of handing make it a robust and easy decapod to bleed and manipulate.
It has few, if any, known lethal pathogens and its robustness has enabled it to spread
to many areas of the globe, where it is becoming to be considered as an invasive pest.
C. maenas expresses a type I crustin; in fact it was the first WFDSC domain-
containing AMP to be found and purified from any invertebrate (Relf et al., 1999).
Cloning and sequencing of this protein, subsequently designated the name,
‘carcinin’, (Brockton and Smith, 2007) revealed its relationship to glycine-rich
WFDSC domain-containing AMPs in other decapod species (Smith et al., 2008).
Curiously, carcinin has an unusual pattern of gene expression in vivo following
bacterial challenge or temperature change (Brockton and Smith, 2008) but more
importantly, in crabs, crustin-type genes are by far the most highly expressed AMP
in the haemocytes (Sperstad et al., 2010), making them not only prominent defence
molecules but also ones easily and reliably detected at the protein level by immuno-

2. Materials and methods

2.1. Animals
Specimens of adult C. maenas were caught in creels laid in the Forth Estuary,
Scotland. Only crabs at moult stage C4T, i.e. those that are fully-grown and past the
terminal moult as defined by Drach (1939) and Crothers (1967), were used for
experiments. These animals ranged in size from \textit{ca} 50 to 75 mm carapace width. They were maintained in seawater tanks at \textit{ca} 10 ± 3 °C and \textit{ca} 32.5 ± 1.5 °/oo salinity for no longer than 10 days before use. The animals were fed twice per week with commercial fish pellets or fresh mussels.

2.2. Bleeding and haemocyte separation

Haemolymph (2 mL) was extracted from the crabs and diluted in 2.5-3.0 mL of marine anticoagulant (MAC) as described previously in Söderhäll and Smith (1983). For experiments requiring unseparated haemocytes, the diluted cells were washed in 0.22 µm filtered 3.2 % NaCl and the concentration adjusted to \textit{ca} 6 x 10^5 mL^-1. For experiments on individual populations of each haemocyte type, 2 mL amounts of freshly drawn diluted haemolymph were loaded onto 9 mL pre-formed 60 % continuous Percoll gradients made up in 0.22 µm filtered 3.2 % NaCl. These were centrifuged at 3,000 x g for 10 min to generate bands of hyaline, semi-granular or granular cells (Söderhäll and Smith, 1983). Prohaemocyte populations were obtained and isolated as in Roulston and Smith (2011). Haemocytes, whether used separated or un-separated, were always kept cool on ice and processed immediately. Unless otherwise stated all chemicals and reagents were obtained from Sigma-Aldrich (Irvine, UK).

2.3 Purification of carcinin

Haemolymph from 24 adult crabs was extracted as in 2.2 above, except that the MAC used was supplemented with the protease inhibitor, phenylmethanesulfonyl fluoride (PMSF) dissolved in dimethyl sulfoxide (DMSO) to a final concentration of 1 mM. The haemolymph samples were pooled and then centrifuged at 1,900 x g for 10 min (4 °C). After discarding the supernatant, the cell pellet was re-suspended in a volume of ice cold 50 mM sodium phosphate buffer (pH 6.5) containing 1 mM PMSF approximately twice the volume of the packed cell volume of the pellet. The haemocytes were then vortexed (5 x 2 min bursts) to release the cytoplasmic contents. The haemocytes were cooled on ice for ten minutes between each burst. The disrupted haemocytes were finally centrifuged at 40,000 x g (4 °C) for 22 min. The resulting haemocyte lysate supernatant (HLS) was collected and its protein concentration was determined using the Bradford assay (Bradford, 1976). Typically
HLS samples derived from 24 crabs contained a total protein concentration of ca 9-10 mg mL\(^{-1}\).

Carcinin was purified from the HLS by liquid protein chromatography on a ÄKTA FPLC system (G.E. Healthcare Life Sciences, Bucks, UK). The procedure was to load 10 mL of HLS onto a Mono S 5/50 GL cation exchange column (GE Healthcare Life Sciences) equilibrated with 50 mM sodium phosphate buffer at pH 6.5. This was eluted with 50 mM sodium phosphate buffer (pH 6.5) containing 1 M NaCl. The salt gradient was increased from 0-100 % over 20 min. Fractions of 1 mL were collected and the protein concentration in each was determined by Bradford assay. Fractions containing high levels of protein were subject to a further purification on a Superose 6 10/300 GL gel filtration column (GE Healthcare Life Sciences). Equilibration and elution were again performed using 50 mM sodium phosphate buffer (pH 6.5). As the FPLC UV detector revealed single peaks matching carcinin in fractions 19 and 20 on the gel filtration chromatograph, these fractions were collected and subjected to SDS-PAGE and staining with Coomassie Blue R-250 (BioRad, Hertfordshire, UK).

These produced two close bands of approximately 11 kDa (Supplementary Information Figure 1a), values close to those expected for native carcinin (Relf et al., 1999). Each band was excised and subjected to in-gel digestion (Shevchenko et al., 1996) using a ProGest Investigator digestion robot (Digilab, Champaign, USA) followed by nLC-ESI-MS mass spectrometry, performed by the Mass Spectrometry Unit at the University of St Andrews, which confirmed that both bands were carcinin, presumably as isoforms (Supplementary Information Figures 1b, c).

2.4. Anti-carcinin antibody production

Polyclonal rabbit antibody was prepared and purified from 1 mg of purified freeze-dried pure carcinin by a commercial company (Davids Biotechnologie, Regensburg, Germany) and the resulting product tested for cross reactivity with carcinin in fresh HLS by SDS-PAGE and Western blotting. High resolution SDS page was performed as described by Relf et al. (1999), using a 16 % separating gel, a 10 % spacing gel and a 4 % stacking gel (Schägger and von Jagow (1987). A mini Trans-Blot® Cell (Bio-Rad), with TTBS (Towbin transfer buffer with SDS: 25 mM Tris, 192 mM glycine, 20% methanol (v/v), 0.025–0.1 % SDS, pH 8.3) was used for blotting on a nitrocellulose membrane at 20 volts for 2.5 hours. The membrane was washed and
blocked overnight with 3% bovine serum albumin (BSA) solution in TTBS. Both the anti-carcinin polyclonal antibody and rabbit pre-immune serum were diluted in 3% BSA solution in TTBS in different ratios: 1:10,000, 1:50,000 and 1:100,000. Primary incubation was for 1.5 h, followed by three washes in TTBS, each for 5 min. Goat anti-rabbit alkaline phosphatase (AP)-tagged secondary antibody was added at the same dilutions as those listed above, and then incubated for a further 1.5 h. The membranes were again subjected to three washes before addition of alkaline phosphatase substrate solution. This comprised a mix of 100 µL of a 15 mg mL⁻¹ solution of 5-bromo-4-chloroindolyl phosphate (BCIP) (made up in dimethylsulfoxide [DMSO]), plus 100 µL of nitroblue tetrazolium (NBT) solution (30 mg in 0.7 mL DMSO and 0.3 mL distilled water) and 10 mL of alkaline phosphate colour development buffer (2.5 mM MgCl₂ in 100 mM Tris base pH 9.5). After the signal developed, the nitrocellulose membrane was washed with TTBS and imaged using the ChemiDoc XRS+ system (Bio-Rad). Three controls were included, namely: (i) no primary or secondary antibodies; (ii) secondary antibody only; (iii) pre-immune rabbit serum substituted for the primary antibody. Controls (i) and (ii) used buffer in place of the relevant antibodies. The blots showed that the anti-carcinin antibody bound both of the two bands of carcinin (depicted in Supplementary Information Figure 1d) and no other proteins in HLS, thereby demonstrating that it exclusively recognized both isoforms of carcinin.

2.5. Immunocytochemistry and immunohistochemistry

The localisation of carcinin in individual haemocyte types and tissue sections taken from at least three healthy crabs was determined by indirect immunostaining. For analysis of the haemocytes, individual 200 µL amounts of separated or un-separated cells, prepared from at least five crabs as described above, were cyto-centrifuged on to glass slides for 3 minutes at 250 rpm (7 xg) on a Shandon Cytospin 3 (Thermo-Fisher Scientific, UK) at room temperature. The preparations were then fixed with 4% paraformaldehyde in 3.2% NaCl for 30 min followed by permeabilization of the cells with Triton-X 100 (3 min) and blocking of endogenous antigens by overnight incubation at room temperature using 10% goat serum plus 10% bovine serum albumin in phosphate buffered saline (PBS) as the blocking reagent.
The fixed haemocyte preparations were then incubated with the carcinin-specific rabbit antibody (diluted 1:100 in blocking serum) for 90 min. The slides were then re-washed 3 times in PBS (5 min each) and incubated for a further 90 min in secondary antibody (goat anti-rabbit tagged with FITC; diluted 1 in 100 in blocking solution). Also included with the secondary antibody solution were 5 µM Draq 5 (BioStatus Ltd, Leicestershire, UK) (excitation 647 nm; emission 681 nm) to reveal DNA and 20 µM rhodamine phalloidin (excitation 540 nm; emission 565 nm) (Thermo Fisher Scientific, Paisley, UK) to identify actin. Each slide was given another 3 washes of 5 min in PBS supplemented with 3 % bovine serum albumin before mounting in Vectashield (Vector Laboratories, Peterborough, UK). Control slides comprised preparations without primary or secondary antibodies, samples incubated with secondary antibody only and preparations treated with rabbit sera instead of primary antibody. For each control, 3 % bovine serum albumin in PBS was substituted for the relevant antibody solution. The stained haemocytes were examined by confocal microscopy with a Leica (DMIRE2) TCS2 confocal microscope (Leica Microsystems, Milton Keynes, UK). Images were captured via Leica software and processed using Image J (National Institutes of Health, USA).

To investigate the distribution of carcinin in the main body organs, samples of gill, heart, hepatopancreas and posterior midgut caecum, were excised from three crabs freshly killed by injection of 4 mL of 2.5 % glutaraldehyde in 3.2 % NaCl as in Robb et al. (2014). Testes and ovaries were obtained from three male and three female animals respectively. Additional tissues, other than those specified above, were not extracted because the organs were either too small or too fragile to obtain intact. All the excised tissues were immediately fixed in fresh 2.5 % glutaraldehyde for 24 h. The fixed samples were then dehydrated in a graded series of ethanol and cleared with Histo-Clear (National Diagnostics, Yorkshire, UK) in a Shandon Duplex Tissue Processor. The tissue samples were finally embedded in paraffin wax with a Shandon Histocentre 2 Embedding Centre and sections of 4-5 µm thickness were cut before mounting on glass slides and processing for histology and immunostaining. Prior to immunohistochemistry, the sections were rehydrated and permeabilized, as above. Blocking of endogenous antigens was as described above, but with the additional inclusion of 30 % levamisol (Vector Laboratories) diluted with PBS to block any endogenous alkaline phosphatase. The slides were then washed 3 times in PBS (5
min each) before incubation with the carcinin-specific rabbit antibody at the same
dilution and time as for the haemocytes (above). Following a further three washes in
PBS, the sections were incubated with the secondary antibody (goat anti-rabbit
tagged with alkaline phosphatase) at a dilution of 1:100 in blocking solution. Each
slide was re-washed 3 times again and then incubated for 10 min in the substrate
solution, comprising 100 µL of the BCIP solution and 100 µL NBT added to 10 mL
of development buffer, as in Section 2.4 above. With this substrate solution, carcinin
is visualised as a deep blue colouration. After washing the slides in PBS 3 more
times the sections were dehydrated through an increasing ethanol series and then
finally mounted with Histomount (National Diagnostics, USA). To map organ
morphology, additional sections were cut and stained with haematoxylin and eosin to
reveal the inner architecture of these tissues. The fine structures on these slides were
identified with reference to Johnson (1980). All samples were examined using a
Zeiss Axiophot light microscope. Images were captured with ZEN image software.

2.6. Experimental manipulation of crabs

To further investigate changes in the presence and distribution of carcinin in the
reproductive tissues, eyestalk ablation was performed to provoke gonadal
development (Quackenbush, 1986). Eyestalks secrete the neuroendocrine factors that
prevent gonad development and molting, so ablation effectively deprives the
animals of these factors. Whilst this has little effect on male crabs, in females it
results in an increase in the level of ecdysteroids (molting hormones) that stimulate
ovarian development (Chan, 1995; Subramoniam, 2000). In the present study, the
procedure was carried out on both males and females; the males being used as
controls for injury and wounding. For both sexes, groups of three crabs were pre-
chilled to 4 °C to make them quiescent and to reduce blood loss. They were were
then subjected to either unilateral (i.e. a single eyestalk) or bilateral (i.e. the two
eyestalks) ablation. The procedure entailed swabbing the areas above the X organs
with 70 % ethanol, and then cutting transversally across the middle of the ocular
peduncles with sterile scissors. The cut surfaces were immediately treated with
antibacterial ointment (1 % fusidic acid in a sterile base) after which the animals
were allowed to recover for 2 h at 4 °C in 0.22 µm filtered Instant Ocean (Aquarium
Systems Ltd, Cheshire, UK). They were then allowed to return gradually to ambient
temperature (10 ± 3 °C). Non-ablated male and female crabs were similarly
maintained as controls. Water was changed every 48 h before the crabs were
sacrificed and the gonads were excised and weighed after five days. The
gonadosomatic index (GSI) was calculated to estimate gonad maturation for each
crab using the following equation:
\[
\text{GSI} = \frac{\text{gonad weight}}{\text{body weight}} \times 100
\]
After the initial surgery, the excised parts of each eyestalk were fixed in Davidson’s
solution for 48 h then immersed in 70 % ethanol before full dehydration and clearing
as described in 2.5 above. Glutaraldehyde was not used for fixation because the
eyestalks in crabs are partially calcified. Additional peduncle material, ca 2-3 mm
thick, was sliced from the top of the severed eyestalks remaining on the crab bodies
at 5 days to ascertain if carcinin is associated with wound repair and tissue
regeneration of this structure. The slices were fixed and dehydrated as above. All the
peduncle samples were then processed for wax histology and immunostaining as
described in Section 2.5 above.

3. Results

3.1. Localisation of carcinin in circulating haemocytes in vitro

Immunostaining with the anti-carcinin antibody showed that freshly harvested un-
separated haemocytes give strong signals in the cytoplasm of a proportion (ca 15 %)
of the cells (Figure 1a). The staining was often seen to be so intense as to obscure the
cytoplasm and sometimes also the nucleus (Figure 1a). A smaller proportion (ca 10
%) showed a variable degree of less intense and more granular staining, with the
remainder (ca 75 %) giving no signal at all (Figure 1a). Based on the size, shape and
relative proportion in the mix, the cell types would roughly correspond to the
granular, semi-granular, and hyaline cells, respectively as described by Smith and
Ratcliffe (1978). Within the unstained cell population a few haemocytes were small
and had a thin ring of cytoplasm around the central nucleus (Figure 1a), typical of
prohaemocytes (Roulston and Smith, 2010).

Further analyses of the four highly enriched haemocyte populations separated on
Percoll gradients confirmed that the haemocytes staining most strongly for carcinin
were the granular cells (Figure 1b). The extent of co-localisation of the signal with
rhodamine phalloidin confirmed its intracellular location (Figure 1b). Haemocytes from the semi-granular cell fraction of the Percoll gradients exhibited less and more variable intensity of staining, with the signal largely confined to cytoplasmic inclusions, and rarely showed co-localisation with rhodamine phalloidin (Figure 1c). By comparison, the cytoplasm of haemocytes from the hyaline cell fraction remained unstained for carcinin, although a variable number (up to approximately 30%) of these cells displayed a small amount of extracellular carcinin on the outside of the plasma membrane (Figure 1d).

With the prohaemocytes, the enrichment and two-step isolation procedures enabled a greater number of these cells to be examined than would have been possible with freshly drawn haemolymph or single step separation alone, and confocal microscopy established that there are two patterns of staining within this population of haemocytes. The majority were carcinin-negative (Figure 1e) but a few showed some granular staining inside their cytoplasm (Figure 1f).

For all haemocyte types, the pattern of staining was repeated in samples obtained from each of the crabs used.

3.2. Localisation of carcinin in gills, heart, hepatopancreas, midgut caecum, gonads and eyestalk in vivo

Immunohistochemical staining of various organ tissues excised from C. maenas consistently showed that a clear signal for carcinin is detectable in circulating haemocytes in situ in all animals used. Figure 2a shows an example of a group of haemocytes residing in the gill. At high magnification the pattern of the distribution of the stain enabled the main haemocyte types to be distinguished consistent with those seen in isolated haemocytes in vitro. Granular and semi-granular cells in particular were discernable by their degree of granular staining with the alkaline phosphatase label. At lower magnification, the gills were seen to be well populated with stained haemocytes (Figure 2b) but there was no other evidence of carcinin in the lamellae (Figure 2c). Carcinin was also absent from the musculature and internal sub-structures of the heart in each of the three crabs tested (Figure 2d), although weak staining was discernable in the capsules surrounding the outer edges of this
organ (Figure 2e). Otherwise the haemocytes were the only cells seen to display strong staining with alkaline phosphatase, and these were usually found in the outer regions of the tissue (Figures 2d, e). Analyses of the hepatopancreas similarly revealed that the only cells to show strong staining for carcinin were the haemocytes perfusing the haemal sinuses between the tubules and the associated interstitial connective tissues. Carcinin was absent from the internal matrix of the hepatic lobules, the secretory tubules and the tubule lumens (Figures 3a-d). Instead, it was present only as a thin ring on the outside of the hepatopancreas capsules (Figure 3a-d) or as weak patches along parts of the connective tissues on the outer edges of the tubules (Figures 3b-d). Interestingly, in these patches, higher magnification revealed clusters of small dark blue spots in close proximity to stained haemocytes (Figure 3d). These resemble carcinin-positive granules discharged from granulated cells, indicating that carcinin can be deposited on the tissues by exocytosis from granular haemocytes. The distribution of carcinin in the posterior mid-gut caeca followed similar patterns, in that the only positively stained cells were haemocytes present in the interstitial spaces (Figures 3e). There was little evidence of carcinin in association with the caecum basement membranes but carcinin-positive haemocytes were noticed to be in the process of disgorging densely blue material to the extracellular environment (Figure 3f-g). No variations in the staining patterns were observed between the individual crabs.

A different picture emerged for the gonads. In the testes, a positive signal for carcinin was clearly evident not only in haemocytes but also in the connective tissues between the seminiferous lobules and in parts of the epithelia (Figure 4a). It was also evident as a thin layer on the outer edges of the basement membranes but was absent from the lobules themselves, the spermatogonia, the spermatocytes and the spermatids (Figure 4b-d).

Ovaries by contrast, exhibited very strong staining within the ovarian capsules, the thin pavement epithelia of the capsules and some of the developing oocytes, particularly those at the outermost parts of the organs (Figure 5a, c-d). Patches of carcinin were also observed in connective tissues surrounding the developing oocytes and their associated accessory cells within the germinal zone (Figure 5b, c). The signal seen in the epithelia around some of the oocytes in the vicinity of the germinal
centres may have been deposited by the haemocytes as carcinnin-positive cells were
commonly observed in very close contact with the epithelia of some oocytes with
some appearing to be in the process of depositing stained granular material on to the
surfaces of them (Figure 5d). More remarkably, carcinnin was further present, to
varying degrees, within the cytoplasm of some, but not all, oocytes near to the
ovarian walls (Figure 5a). In the more deeply stained oocytes, even the nuclei
appeared to contain carcinnin (Figure 5a). Again, the distribution of carcinnin in testes
and ovaries was consistent within the gender groups.

The eyestalk peduncles were the only other body organ in which carcinnin was
detected at appreciable levels. Samples taken immediately after ablation showed a
well-organised architecture comprising an outer acellular cuticle overlying a thin
layer of cells, some of which appear to be melanised (Figure 6a). The sub-cuticular
endodermal regions beneath this were seen to contain a loose network of
interconnected cells, which include neurons (lamina ganglia) and haemocytes
amongst others (Figure 6a). Carcinin occurred mainly in the cuticular capsules where
it had a distinct pattern of distribution, appearing as patches along the exocuticles
and as series of striated bands in the endocuticle (Figure 6b, c). As depicted in
Figures 6b, c, these endothelial striations show decreasing staining intensity from the
outer region inwards, reminiscent of growth rings in tree trunks. The only other
staining seen inside the cellular matrices of the inner part of the peduncles was in
haemocytes (not shown).

3.3. Localisation of carcinnin following eyestalk ablation
Macroscopic observations of the ablated C. maenas confirmed the animals were
active, feeding and in good condition five days after surgery, so were not seriously
handicapped by the treatment. As expected, ablation of the eyestalks had a major
impact on the size, texture and colour of the ovaries in female crabs five days after
surgery, but had no observable effect on the other body organs or testes in males
(Figures 7a-c). In particular the ovaries became more conspicuous and changed from
creamy white to yellow and orange in unilaterally and bilaterally ablated animals,
respectively, compared to the un-ablated controls. Overall, the effect was much
stronger and more pronounced in the individuals in which both eyestalks were
removed (Figures 7a-c). These changes were quantified in terms of their GSI values
as 1.02 for the un-ablated crabs, 1.29 for the unilaterally ablated ones and 4.21 for the bilaterally ablated specimens. These values show that ablation had successfully driven gonadal maturation in the female crabs. As expected, these macroscopic changes were accompanied by marked alterations in the histological characteristics of the ovary tissues, especially a shift in the oocyte profile from the presence of both pre-vitellogenic and vitellogenic stages in the un-ablated crabs to only vitellogenic stages in the treated animals (Figures 7d-f). The unilaterally ablated animals tended to have mostly early vitellogenic oocytes in the ovary (Figure 7e) whereas in the bilaterally ablated females the ovaries were packed with fully mature ova containing yolk bodies (Figure 7f). Regarding carcinin distribution, there was a marked reduction in its level and presence throughout the ovaries in crabs that underwent unilateral eyestalk ablation (Figure 7e). With the exception of a few haemocytes seen in the extra-oocyte vascular spaces, which were well stained, there was very little evidence of staining in the connective tissues between the developing oocytes (Figure 7e). A few oocytes showed weak internal staining but otherwise carcinin was not seen in association with the surrounding epithelia (Figure 7e). Staining was totally absent from the ovaries of the bilaterally ablated animals (Figure 7f) but, more remarkably, these tissues also appeared to be devoid of haemocytes, or at least lacking blood cells displaying positive blue staining (Figure 7f). This could not have been due to haemolymph loss through the surgical procedures as no other organs were similarly affected (data not shown). The only remaining carcinin in these bilateral ablated females was occasionally noted around the ovarian capsules (Figure 7f).

Five days after ablation, however, the eyestalk cuticular capsules seemed to be regenerating despite the structures being ragged and torn with their inner cores unstructured and dense (Figure 6d). Interestingly the regenerating areas were intensely stained for carcinin (Figures 6e-f) with almost the entire exo- and endo-cuticular areas plus the inner cellular matrices strongly staining blue (Figure 6e). The re-growing inner tissues were also infiltrated with cells, presumably haemocytes, strongly positive for carcinin (Figure 6f).
4. Discussion

There are a growing number of research papers reporting expression of genes encoding immune-relevant proteins in decapod crustaceans with AMPs, including members of the crustin family, popular targets (see review by Smith and Derynda, 2015). Many of these studies present data showing that transcripts of crustins are present, to varying degrees, in a wide range of tissues and body organs of unchallenged animals. These investigations include those on crab: Yue et al. (2010) and Mu et al. (2010); shrimp: Sun et al. (2010) and Anthony et al. (2011), as well as crayfish (Yu et al., 2016). Such results are often, understandably, interpreted as evidence that the organ or tissue itself expresses the protein. Here we show that carcinin is prominent in the haemocytes, but scarce in several of the body organs in healthy, un-stimulated crabs.

In haemocytes, carcinin is differentially distributed across the various sub-populations, being present only in those haemocytes that contain granules. This distribution of carcinin in the blood cells tallies with the findings of a previous study on the spider crab, Hyas areneus, which determined that the gene encoding a Type I crustin, is expressed over 2,000 times more highly in the granular haemocytes than in the hyaline cells, but only 30 fold more so in the semi-granular cells, again in untreated animals (Sperstad et al., 2010). In the present study we confirm that carcinin in C. maenas is absent from the cytoplasm of the hyaline haemocytes and agranular prohaemocytes, although in vitro it may be external to the plasma membrane of some of these cells. It is likely that the protein was derived from other haemocytes as it is well established that the semi-granular haemocytes of decapods are labile and readily discharge their granules to the exterior in vitro (Bauchau, 1981; Smith and Söderhäll, 1983; Söderhäll et al., 1986). In the present study degranulation could well have been triggered during the bleeding and cell separation procedures. The presence of carcinin in granules of some prohaemocytes is also noteworthy because it provides further evidence that there may be two separate precursor haemocyte lineages in decapods, as previously suggested for shrimp by van de Braak et al. (2002) and subsequently for crab by Roulston and Smith, (2011). Surprisingly, carcinin was largely absent from gill, hepatopancreas, heart and mid-gut caecum taken from the un-challenged specimens of C. maenas. Where carcinin
was seen, it tended to be on the outer surfaces of these structures and more conspicuous in haemocytes populating these organs rather than the tissues themselves. As haemocytes were observed disgorging carcinin-positive material at the outer surfaces in contact with the haemolymph, we suggest that the haemocytes are the main source of the carcinin staining apparent in these organs. This raises questions as to the extent to which crustin transcripts, detected in the organs of unchallenged animals by previous authors (cited above) actually originated from tissues themselves or from haemocytes populating them. That there is no consistent pattern of expression levels for individual studies, decapod species, treatments or tissues (reviewed by Smith and Dyrynda, 2015), may be a reflection of this. At present, it is unclear if the distribution of carcinin in the body organs of *C. maenas* would be different in animals that had received an immune challenge with bacteria, virus or other immune-activating substances compared to untreated ones. So far, our preliminary findings with *C. maenas* (unpublished) lead us to consider that, while the internal body organs receive an influx of haemocytes from the haemolymph following lipopolysaccharide injection, the tissues themselves do not seem to express carcinin *de novo* as a response.

In contrast to the gill, heart, hepatopancreas and mid-gut caecum, carcinin is present in the eyestalk peduncles. Its occurrence in the endo-cuticle is in keeping with previous studies on crabs that noted the presence of crustin signatures in EST libraries prepared from eyestalks of the crab, *Portunus trituberculatus* (Liu *et al*., 2011; Cui *et al*., 2012). As yet it is unknown whether these transcripts originated from the peduncle tissue itself or from the haemocytes that pervade it. In *C. maenas*, the striated pattern of staining in the excised peduncules closely resembles that of the growth bands described for the peduncles in other decapod species by Kilada *et al*. (2012). These bands are believed to form annually in calcified regions of the peduncle in decapods and are often used to estimate the age of the animal (Kilada *et al*., 2012), so it is possible that crustins are synthesised or deposited there by haemocytes as the crab ages and passes through its moult cycles. We propose that the striations of carcinin detected in the peduncles from *C. maenas* represent individual moult events that occurred during the animals’ lives. Mature adult crabs generally moult once per year (Chang, 1995) and during the process the eyestalks, along with the antennae, mouthparts, gills and legs, are withdrawn from the old exoskeleton and
a new epidermis forms beneath (Crothers, 1967). After the old shell has been cast, the new, soft, epidermis underlying it is finally exposed to the outside environment. Until it hardens, however, the animal is left very vulnerable to injury and infection. It is therefore highly likely that antimicrobial proteins, including crustins, come to be associated, one way or another, with the un-calcified epidermis in order to confer some protection against microbial incursion.

In addition to its location in the eyestalk, carcinin was seen to be conspicuous in the gonads although its presence was more marked in ovaries than in testes. Indeed, in un-ablated crabs both the ovarian tissue itself and some of the developing oocytes near the periphery of the capsules show the strongest staining of all tissues examined except for the haemocytes. Indeed the level is greater than that which would be expected through deposition from haemocytes alone. We therefore believe that synthesis of carcinin can and does occur in the ovary; a view that agrees with the findings of Zhang et al. (2007) and Sun et al. (2010), who reported expression of crustin genes in ovary of untreated shrimp. In crabs, oocytes arise from oogonial cells, and pass through four development stages before maturing into mature eggs (Ravi et al., 2013). These four stages are marked by an increase in cell size with a concomitant decrease in the nuclear:cytoplasmic ratio (Sharifian et al., 2015). There is also a transition from a pre-vitellogenic state to a vitellogenic stage as the oocytes move away from the germinal centre towards the periphery of the ovary (Sharifian et al., 2015). Fully mature eggs are large and packed with yolk bodies (Ravi et al., 2013). In our study, carcinin tended to be located in the larger, vitellogenic oocytes near the outer edges of the tissues. Unfortunately the pre-vitellogenic oocytes in these females were too small to visualise with any degree of certainty but the lack of clear signals in the central region of the ovaries leads us to suppose that they are devoid of carcinin. We do not know why carcinin associates with some of the vitellogenic cells but the heavily vacuolated and fragmented appearance of the carcinin-positive oocytes leads us to suppose that it may play a role in the degeneration, resorption or clearance of defective or redundant ones.

Removal of the eyestalks clearly drove oocyte maturation but, curiously, very little carcinin remained in the fully mature yolk filled eggs of the bilaterally ablated females five days post surgery. Where present it appears to be derived from granular
material originating from haemocytes. Thus, we conclude that carcinin is confined
to oocytes in later vitellogenic development, as it is largely absent from mature eggs.

It is reasonable to assume that the carcinin seen in *C. maenas* ovary serves in an
antimicrobial capacity and therefore should have value in protecting the maturing
oocytes from infection. This would be important as mating occurs in crabs when the
female has moulted and is susceptible to microbial incursion through the soft, un-
calcified epidermis. Certainly, several reports already exist that antimicrobial
proteins are associated with the reproductive organs of crabs (Jayasankar and
Subramoniam, 1999; Huang et al., 2006; Wang et al., 2007; Qiao et al., 2016; Xu et
al., 2011a, b) as well as in some other arthropods (Samakovlis et al., 1991). Indeed
there are some WFDSC-domain containing proteins, particularly eppin, that occur in
the testes and/or ovaries of mammals (Yenugu et al., 2004; Trexler et al., 2002; see
also review by Bingle and Vyacarnam, 2008). However, whilst the notion of
gonadal disinfection is attractive and compelling, it does not fit with our observations
that carcinin almost entirely disappears from the fully mature eggs and ovaries of
ablated female crabs.

The vast majority of decapod crustins, described in the literature are known for their
antibacterial activities (Smith et al., 2008; Smith and Dyrynda, 2015) with, as yet, no
other functions definitely proven. What is puzzling about these proteins is that their
ability to kill or inhibit the growth of bacteria tends to be much weaker than that of
other AMP families in the Pancrustacea, and that the proteins mainly act against
Gram-positive strains (Smith et al., 2008; Smith and Dyrynda, 2015). In recent years,
however, some publications have started to provide indications that, in addition to
disinfection, crustins might also have some other physiological effects. For example,
a few crustins, primarily Type IIIIs (i.e. those that have a relatively simple structure in
comprising only one WFDSC domain and a short proline-arginine sequence together
with the signal sequence), have proteinase inhibitory properties (Smith et al., 2008).
Further, some Type IIIs (which possess not only a cysteine rich region but also a long
glycine-rich domain adjacent to the signal region) are reported to be involved in
haematopoiesis (Fagutoa et al., 2012; Chang et al., 2013) or have possible opsonic
effects (Liu et al., 2015). Surprisingly, too, expression of a carcinin-like transcript in
the swimming crab, *Portunus pelagica*, has been found be 7-8 times higher in inter-
moult crabs than at ecdysis, with intermediate levels at pre-and post moult stages (Kuballa and Elizur, 2008). This finding, in particular, is at odds with the notion that the prime role of crustins is in antimicrobial protection because ecdysis is the period when the animal has most need of its host defenses.

It is well known that decapod crustaceans are able to regenerate certain parts of their body (especially appendages and eyestalks) after autotomy or injury. In the present study, the presence of regenerating epithelial tissue seen at the cut surfaces of the peduncles demonstrate that recovery would have been well underway before sacrifice. However, at present it is unclear what purpose carcinin serves in this process. The dramatic increase in the amounts of the protein in the capsular walls at this time point supports the view that carcinin has some involvement in the healing or regeneration processes. Certainly crustins have been reported to be present in regenerating tissues, with PET-15, a Type I crustin transcript in the spiny lobster, *Panulirus argus*, in particular, expressed at sites of olfactory sensory neuron proliferation (Stoss et al., 2003). Likewise, another Type I crustin gene (designated DW176897) is expressed in regenerating limbs of the fiddler crab, *Celuca pugilator* (Durica et al., 2006). It is also noteworthy that transcripts of three crustin isoform genes have been identified in the heart, intestine, haemocytes, gills and hepatopancreas of planktonic phyllosoma (larval) stages of *Panulirus japonicus*, with a fourth isoform detected in nerves (Pisuttharachai et al., 2009). Interestingly, in humans, a gene, encoding a WFDSC-domain containing protein, namely WFDSC-2 (also known as human epididymis protein, HE4), is over-expressed in cancerous ovarian tissue (Hellström et al., 2003). A more recent study has now shown that the protein enhances proliferation of the cancer cells by regulating apoptosis (Chen et al., 2013). Furthermore, in rodents a uromodulin like-1 WFDSC domain-containing protein accelerates age-related ovarian degeneration (Wang et al., 2012). Given that carcinin is not only expressed in regenerating eyestalk, which is well supplied with neural fibres, but is also prominent in ovary and late-stage vitellogenic oocytes, it is not unreasonable to propose that it, and probably other crustins, have some role(s), as yet unknown, in cell and/or tissue repair or regeneration. Further proteomic studies on this family of proteins in other decapods are clearly warranted.

Figure legends

Figure 1. Carcinin distribution in circulating haemocytes
Cyto centrifuge preparation of haemocytes from C. maenas stained with anti-carcinin antibody. Green staining (FITC) reveals carcinin, blue (Draq 5) reveals DNA and red (rhodamine phallloidin) shows actin. (a) Freshly harvested un-separated haemocytes. Note that carcinin is present only in some cells to varying extent. Many cells remain unstained. H = hyaline cells; SG = semi-granular cells; G = granular cells; PH = prohaemocytes. (b-f) Haemocytes separated on Percoll gradients: (b) Granular cell showing co-localisation of carcinin with actin (yellow staining). (c) Semi-granular cell in which carcinin tends to occur around the nucleus and with less co-localisation with actin than in the granular cells. (d) Hyaline cell with no conspicuous staining for carcinin within the cytoplasm. Peripheral staining outside of the plasma membrane may be from carcinin released from semi-granular or granular cells during cell separation. (e) Agranular prohaemocyte lacking carcinin. (f) Granulated prohaemocyte with some carcinin staining evident in the surrounding cytoplasm.

Figure 2. Carcinin distribution in gill and heart
Paraffin wax sections of gill and heart extracted from healthy adult crabs, stained with anti-carcinin antibody using alkaline phosphatase label (dark blue). (a) Part of a gill filament showing haemocytes in vivo. The unstained cells are likely to be hyaline cells (H), with patchily stained cells being semi-granular cells (SG) and the more densely stained granular haemocytes (G). (b) Primary gill lamella showing the conspicuous presence of carcinin in the haemocytes (arrow); (c) Secondary lamellae showing carcinin located only in haemocytes (arrows); (d) Cardiac tissue again revealing the absence of carcinin staining except in haemocytes (arrow). (e) Haemocytes staining positively with carcinin clustered at the periphery, whilst the heart tissue itself remains largely unstained apart from weak signals surrounding the outer edge of this organ (arrows).

Figure 3. Carcinin distribution in hepatopancreas and mid-gut caecum
Paraffin wax sections of hepatopancreas and gut excised from healthy adult crabs and stained with anti-carcinin antibody using alkaline phosphatase (staining dark blue) as label. (a-d) Hepatopancreas. Note the absence of stain in the matrix of the
organ and the presence of strong staining of the haemocytes perfusing the tissue between the tubules. Weaker staining is visible at the outer edge of the organ in places and in the interstitial connective tissues (arrows). Figure 4. Carcinin distribution in testes
Paraffin wax sections of testes extracted from healthy adult male crabs and stained with anti-carcinin antibody using alkaline phosphatase. A positive signal is seen as intense blue. (a-b) Low power plans showing the seminiferous lobules (SL) that do not give a positive signal for carcinin although staining is clearly evident as a thin layer on the outer edge of the basement membrane and in the connective tissue between them (arrows). (c, d) Part of a testis showing spermatagonia, spermatocytes and spermatids (Sp). Note only the haemocytes and patches of the epithelium surrounding the spermatogonia show the blue stain for alkaline phosphatase (unlabelled arrows).

Figure 5. Carcinin distribution in ovary of adult intermolt crabs
Paraffin wax sections of ovary extracted from healthy adult female crabs. Carcinin is indicated by blue from alkaline phosphatase stain. (a) Low power plan of an ovarian capsule containing oocytes in various stages of development. Note there is very strong staining around the outer edge of the capsule (white arrow), in the thin pavement epithelium of some oocytes and even in some maturing oocytes near the periphery of the capsule (black arrows). There are also a few nuclei showing positive staining for carcinin (grey arrows). (b) Vitellogenic oocytes showing the presence of carcinin in the connective tissue surrounding the developing oocytes. (c) Vitellogenic oocyte with patches of carcinin on its outer surface (black arrow) and an associated accessory cell (white arrow). (d) Higher power detail of a vitellogenic oocyte in very
close association with haemocytes, some of which appear to be releasing intensely
stained carcinin onto the oocyte surface (arrows).

Figure 6. Carcinin distribution in eyestalk peduncle of unablated and ablated
female crabs
Paraffin wax transverse sections of the eyestalk peduncle excised from adult,
intermoult female crabs. (a) Appearance of the peduncle in a control slide without
carcinin antibody. No blue staining is evident. (b) Appearance of the peduncle at the
time of ablation stained for carcinin with an alkaline phosphatase label (blue).
Carcinin can be seen in a wide band lying between a thin darkly stained layer of
melanin (M) and underneath the outer shell (OS) of the peduncle. (c) Higher power
detail of the carcinin-positive region of the peduncle. Note the blue striations of
carcinin that diminish in width and colour intensity from the outer region inwards.
Each striation represents a previous moult. (d) Haematoxylin and eosin stained
section of the regenerating peduncle 5 days after eyestalk ablation. Note the
fragmented nature of the damaged tissue. (e) Regenerating eyestalk peduncle 5 days
after ablation stained with the alkaline phosphatase label to identify carcinin. The
wound is very intensely stained and with a positive signal extending into the inner
regenerating tissue (RT) of the structure as well as to the outer capsule. (f). Higher
power detail of the regenerating peduncular tissue 5 days post ablation. Note the
presence of haemocytes in the regenerating tissue (RT) outside of the internal
structure (IS). At least one haemocyte (arrow) seems to be depositing carcinin to the
injury area lying between the RT and the IS.

Figure 7. Carcinin distribution in ovary of eyestalk ablated female crabs
(a-c) Dissected female crabs showing changes in the ovary (arrows) following
eyestalk ablation. (a) normal ovary in an un-ablated intermoult female crab: G =
gills, Ht = heart, Hp = hepatopancreas, the asterix indicates the region where the
mid-gut caecum is located. (b) Ovary in a unilaterally-ablated female 5 days post
surgery. The tissue is enlarged and developing a yellow colouration. (c) Ovary in a
 crab subjected to bilateral eyestalk ablation 5 days previously. The ovary is very
enlarged and bright orange in colour due to the accumulation of yolk bodies in the
oocytes. (d-f) Paraffin wax sections of the ovary tissue stained for carcinin with
alkaline phosphate. (d) Ovary from an un-ablated crab showing oocytes at late pre-
vitellogenic stages and a few early vitellogenic stages of maturation. Carcinin is present in the connective tissue surrounding and within some of the vitellogenic oocytes plus their associated accessory cells. (e) Ovarian tissue from a unilaterally ablated animal. The majority of oocytes are vitellogenic but not fully mature. They show little evidence of carcinin staining. Rather the stain is confined to a few haemocytes present in the interstitial spaces. (f) Ovary from a bilaterally ablated female. Note all the oocytes are now fully mature ova full of yolk bodies. There is little or no evidence of carcinin within the ovarian tissue, although there is staining remaining on the ovarian capsule (arrow).
