Abstract

The role of mountain evolution on local climate is poorly understood and potentially underestimated in climate models. One prominent example is East Africa, which underwent major geodynamic changes with the onset of the East African Rift System (EARS) more than 250 Myr ago. This study explores, at the regional East African scale, a molecular approach for terrestrially-based paleo-climatic reconstructions that takes into account both changes in temperature and in altitude, potentially leading to an
improved concept in paleo-climatic reconstructions. Using surface soils collected along pronounced altitudinal gradients in Mt. Rungwe (n=40; Southwest Tanzania) and Mt. Kenya (n=20; Central Kenya), we investigate the combination of 2 terrestrial proxies, leaf wax n-alkane δ²H (δ²H\textsubscript{wax}) and branched glycerol dialkyl glycerol tetraether (br GDGT) membrane lipids, as (paleo) elevation and (paleo) temperature proxies, respectively. At the mountain scale, a weak link between δ²H\textsubscript{wax} and altitude (R² = 0.33) is observed at Mt. Kenya, but no relationship is observed at Mt. Rungwe. It is likely that additional parameters, such as decreasing relative humidity (RH) or vegetation changes with altitude, are outcompeting the expected δ²H-depletion trend along Mt. Rungwe. In contrast, br GDGT-derived absolute mean annual air temperature (MAAT) and temperature lapse rate (0.65 °C/100 m) for both mountains are in good agreement with direct field measurements, further supporting the robustness of this molecular proxy for (paleo) temperature reconstructions. At the regional scale, estimated and observed δ²H data in precipitation along 3 mountains in East Africa (Mts. Rungwe, Kenya and Kilimanjaro) highlight a strong spatial heterogeneity, preventing the establishment of a regional based calibration of δ²H\textsubscript{wax} for paeloaltitudinal reconstructions. Different from that, an improved regional soil calibration is developed between br GDGT distribution and MAAT by combining the data from this study (Mts. Rungwe and Kenya) with previous results from East African surface soils along Mts. Kilimanjaro (Tanzania) and Rwenzori (Uganda). This new regional calibration, based on 105 samples, improves both the R² (0.77) and RMSE (root mean square error; 2.4 °C) of br GDGT-derived MAAT over the global soil calibrations previously established (R² = 0.56; RMSE = 4.2 °C) and leads to more accurate (paleo) temperature reconstructions in the region.
1. Introduction

The East African Rift System (EARS) is one of the best examples of an active rift system. The initial rifting in the area dates back to the Permo-Triassic and Cretaceous (Macgregor, 2015). The development of this complex system with several phases of rifting dramatically changed the East African landscape. Yet its potential influence on the vegetation and local and African climate is hardly constrained. Previous modelling (Sepulchre et al., 2006) postulated that the rise of the EARS should have greatly contributed to the long term aridification of East Africa. However, these simulations only compared 2 extreme scenarios: (i) no elevation and (ii) high elevation – reflecting the lack of a well constrained history of the EARS rise. Moreover, paleo-climate reconstructions in East Africa have long been hampered by 2 challenges: (i) traditional hydrological proxies, such as lake level studies, are influenced not only by changes in the amount of precipitation but also by ambient temperature; (ii) temperature changes are poorly constrained because few sedimentary proxies are sensitive enough to accurately record the small scale temperature variations in tropical lakes (Verschuren et al., 2009).

Recently, novel proxies were developed based on the analysis of fossil organic compounds containing environmental information in their structures. Notably, leaf wax $n$-alkane $\delta^2$H ($\delta^2$H$_{wax}$) was proposed as a (paleo) elevation proxy (Jia et al., 2008) while branched glycerol dialkyl glycerol tetraether (br GDGT) membrane lipids are increasingly used as a (paleo) temperature proxy (Weijers et al., 2007). The combined use of these 2 proxies could thus help to better constrain the relationships between topography and climate in East Africa.
Long chain $n$-alkanes are produced primarily by higher terrestrial plants (Eglinton and Hamilton, 1967) and their $^{2}$H/$^{1}$H ratio, typically expressed as $\delta^{2}$H$_{\text{wax}}$, is linked with the $^{2}$H/$^{1}$H ratio of the plant water source (e.g. Sauer et al., 2001). Because $n$-alkanes are well preserved in the geological archives (Eglinton and Eglinton, 2008) and their hydrogen not easily exchangeable (Schimmelmann et al., 2006), the $\delta^{2}$H$_{\text{wax}}$ is frequently used in paleo-climate studies to track the variability of the $^{2}$H/$^{1}$H ratio of meteoric water ($\delta^{2}$H$_{p}$), as recently reviewed by Sachse et al. (2012). The ‘altitude effect’, described by Dansgaard (1964), is one of the physical parameters impacting the $\delta^{2}$H$_{p}$ and it corresponds to the progressive $^{2}$H-depletion of precipitation along altitudinal gradients due to successive Rayleigh distillation equilibria as the air mass rises. This effect has been observed in precipitation along several mountains across the world (Araguás-Araguás et al., 2000) including 2 equatorial African mountains: Mt. Cameroon (Cameroon; Gonfiantini et al., 2001) and Mt. Kilimanjaro (Tanzania; Zech et al., 2015). The ability of $\delta^{2}$H$_{\text{wax}}$ to track this altitudinal effect was first shown at Mt. Gongga (China; Jia et al., 2008). This relationship was further observed at several mountains in Asia, Oceania and America (e.g. Luo et al., 2011; Ernst et al., 2013; Bai et al., 2015; Zhuang et al., 2015).

Branched GDGTs represent another group of biomarkers increasingly used for paleo-climate reconstructions in terrestrial archives (e.g. Peterse et al., 2011). These membrane lipids (Suppl. Fig.) are ubiquitous in both terrestrial and aquatic environments (Schouten et al., 2013) and are produced by yet unknown bacteria. In soils from across the globe, the relative abundance of the different br GDGTs was shown to depend on environmental parameters (Weijers et al., 2007), leading to the development of global
calibrations between br GDGT distribution and mean annual air temperature (MAAT) and pH (Weijers et al., 2007; Peterse et al., 2012). These compounds can therefore be used as paleo-thermometers. Soil-derived br GDGTs have been investigated along several mountain transects (e.g.; Peterse et al., 2009; Ernst et al., 2013; Anderson et al., 2014) with a high variability in temperature (as temperature decreases with altitude). In the previously published papers, the related br GDGT-derived MAAT were found to (i) be in agreement with local measured MAAT and (ii) relate with altitude (i.e. following the natural temperature gradient), even though a high degree of scatter was observed for some case studies (e.g. Mt. Gongga; Peterse et al., 2009).

The combination of $\delta^2$H$_{\text{wax}}$ and br GDGT provided promising results which significantly expand their potential for (paleo) climate reconstruction. In modern soils, they were found to both correlate with altitude along Mt. Gongga (China, Jia et al., 2008 and Peterse et al., 2009), Mt. Meghalaya (India, Ernst et al., 2013) and the Southern Alps (New Zealand, Zhuang et al., 2015) implying that $\delta^2$H$_{\text{wax}}$ was recording the altitude effect in $\delta^2$H$_{\text{p}}$ and br GDGTs the natural temperature gradient. In geological archives, the approach has been employed to reconstruct the early Eocene elevation and climatic history of the Sierra Nevada (Hren et al., 2010). It was deduced from the analysis of $\delta^2$H$_{\text{wax}}$ from fossil leaves and br GDGTs from the sediment matrix that, during the Eocene Climatic Optimum, Sierra Nevada elevation was high (> 2 km) with warmer air temperature than today. In East Africa, however, altitudinal transects from the southern slope of Mt. Kilimanjaro (Tanzania) was investigated by several groups (Sinninghe Damsté et al., 2008; Peterse et al., 2009; Zech et al., 2015), resulting in inconsistent results. While estimated air temperatures derived from the analysis of br GDGTs were
consistent with the observational temperature data (Sinninghe Damsté et al., 2008), no clear altitudinal trend was observed for $\delta^2$H$_{wax}$ (Peterse et al., 2009; Zech et al., 2015). This prompts the question regarding the relative importance of site (mountain)-related and regional (East African)-related controls on the link between altitude and soil $\delta^2$H$_{wax}$ record.

In the present study, $\delta^2$H$_{wax}$ and br GDGTs were analysed in 60 surface soils along 2 East African mountains – Mt. Rungwe (n=40; Southwest Tanzania; Fig. 1) and Mt. Kenya (n=20; Central Kenya; Fig. 1) – to further test their joint applicability as (paleo) environmental proxies in this climatically sensitive area. Our results were then combined with previously published data for 2 additional East African mountains (Mt. Rwenzori, Uganda, Loomis et al., 2011; Mt. Kilimanjaro, Tanzania, Peterse et al., 2009, Sinninghe Damsté et al., 2008 and Zech et al., 2015) to potentially generate regional calibrations of $\delta^2$H$_{wax}$ variations with elevation and br GDGT variations with temperature. This could improve the precision/quality of regional scale (paleo) elevation and (paleo) temperature reconstructions in comparison with global calibrations. The ultimate goal of this work is to introduce improved tools for terrestrially-based paleo-climatic reconstructions in East Africa that take into account not only temperature but also altitude changes, and which could then be used to reconstruct the evolution of topography and climate dynamics over geological time in the EARS.
2. Materials and Methods

2.1. Study sites

Br GDGTs and n-alkanes were analysed in 40 surface soils collected between 500 and 2800 m along the gentle then steep slope of Mt. Rungwe in 2012 and 2014, and in 20 samples collected between 1900 and 3300 m along the steady gentle slope of Mt. Kenya in 2013 (Table 1). About 50-60 g of soil were collected in the A horizon (0-5 cm) and kept at room temperature before shipping to France by plane.

Mt. Rungwe is located in the Southwest of Tanzania (9° S, 33° E; Fig. 1) and experiences a typical tropical climate, with alternations between a hot and humid (from November to May) season and a colder and drier season (from June to October; Delalande et al., 2008). Natural vegetation along the altitudinal transect belongs to the Zambezian Miombo-type woodland at low altitude and Afromontane vegetation at higher altitude (e.g. Vincens et al., 2003). Agriculture – including banana, rice, cocoa, tea, coffee, maize cultivations – is practiced up to 1500 m leading to partial deforestation of the mountain slopes (Williamson et al., 2014). MAAT was continuously measured with temperature loggers (weather station, DAVIS, Instruments, Hayward, CA, USA) at 540 m, 920 m and 1720 m and varied from 25.6 °C at 540 m to 22.6 °C at 920 m and 16.9 °C at 1720 m, leading to a temperature gradient of 0.7 °C/100 m.

Mt. Kenya is the highest mountain in Kenya (5199 m.a.s.l.) and is located on the equator (0° S 37° E; Fig. 1). The twice-yearly passage of the Intertropical Convergence Zone (ITCZ) leads to a bimodal rainfall pattern characterized by the onset and duration of the long rains (March to May) and short rains (October to November), the other months experiencing a drier climate (Camberlin et al., 2014). Present day vegetation is marked by
five distinguishable altitudinal zones, (Bremond et al., 2008; Hamilton, 1982) from the
mountain forest belt at its base (1960–2500 m.a.s.l.) to Afroalpine at its top (3400–
4200 m.a.s.l.), with Bamboo and Ericaceous zones in between. Based on meteorological
data from weather stations along Mt. Kenya and in Central Kenya (Camberlin et al.,
2014; Kenya Meteorological Department, 1984; Kenya Meteorological Department;
Smith, 1993), temperature lapse rate along Mount Kenya was determined as 0.63 °C/100 m.

2.2. Sample preparation

Samples were frozen and freeze-dried at their arrival in Paris (France) and then
kept at -18 °C prior further treatment. Sample preparation was identical to that detailed
by Coffinet et al. (2014). Briefly, soils were extracted (3 × 5 min) with dichloromethane
(DCM): methanol (MeOH) (9:1, v:v) using an accelerated solvent extractor (ASE 100 –
Dionex; 100°C, 10 × 10⁶ Pa). The extract was separated into 2 fractions through a 2 cm
diam. column of Al₂O₃ (activated overnight at 150 °C) using heptane:DCM (9:1, v:v) and
DCM:MeOH (1:1, v:v) respectively. The 2 fractions were then rotary evaporated, re-
dissolved in 1 ml heptane and centrifuged using an Eppendorf Mini Spin centrifuge (1
min, 7000 rpm) prior to further analysis.

2.3. n-Alkane analysis

\(n\)-Alkanes were analysed at UPMC, Paris, France by gas chromatography coupled
to a mass spectrometer (GC-MS) using an Agilent Network 6890 GC System coupled
with a 5973 Mass Selective Detector, with electron impact at 70eV. 1 µl was injected and
the separation was achieved using a Restek RXI-5 Sil MS silica capillary column (30 m × 0.25 mm i.d., 0.50 µm film thickness) with He as the carrier gas at 1 ml/min flow rate. The GC oven initial temperature was set to 50 °C and then increased to 320 °C at a 4 °C/min. Samples were injected in splitless mode and the injector temperature was 280 °C.

$n$-Alkane hydrogen isotopic composition was measured at Newcastle University, UK using a Delta V+ isotope-ratio mass spectrometer (IRMS, ThermoFisher) connected to a GC Ultra Trace (ThermoFisher), a Finnigan GC Combustion III (ThermoFisher) and a high temperature conversion (HTC) system set up at 1400 °C. The GC oven initial temperature was set to 50 °C and then increased to 250 °C at 15 °C/min and from 250 °C to 320 °C at 5 °C/min. The GC oven was held at 320 °C for 15 min. Every sample was analysed in duplicate and the $^2$H/$^1$H ratio was reported on the VSMOW (Vienna standard mean ocean water) scale to determine compound specific $\delta^2H_{Cn}$ (‰). The H$_3$ factor was measured daily and varied between 2.48 and 2.61 during the course of analysis.

Sample $n$-alkane $\delta^2H$ values were corrected individually using an $n$-alkane standard ($n$-C16 to $n$-C30; mix A5) and 5α-androstan standard (A. Schimmelmann, Indiana University), run at the beginning and at the end of each sample sequence. Standard error of the measurements of the long chain $n$-alkanes (C$_{25}$-C$_{31}$) from this standard mix ranged between 0.3‰ and 1.1‰.

2.4. Br GDGT analysis

Br GDGT analysis was performed at UPMC, Paris, France by high pressure liquid chromatography coupled to a mass spectrometer with an atmospheric pressure chemical ionization source (HPLC-APCI-MS). Samples from Mt. Rungwe collected in 2014 were
analysed with a Shimadzu LCMS-2020, as described by Coffinet et al. (2015), whereas samples from Mt. Kenya and those from Mt. Rungwe collected in 2012 were analysed with an Agilent 1100 series HPLC instrument equipped with an automatic injector and coupled to a PE Sciex API 3000 mass spectrometer, using a procedure described by Coffinet et al. (2014). Similar chromatographic conditions were used on the 2 machines and samples from Coffinet et al. (2014) were re-run with the Shimadzu LCMS-2020 to assess the method reproducibility between the 2 LCMS apparatus (mean errors: 0.03 for MBT, 0.05 for CBT and 0.28 °C for MAAT).

Semi-quantification of br GDGTs was performed by comparing the integrated signal of the respective compound with the signal of a C_{46} synthesised internal standard (Huguet et al., 2006) assuming their response factors to be identical.

The MBT’ (methylation index of branched tetraethers; eq. 1; Peterse et al., 2012) and CBT (cyclisation ratio of branched tetraethers; eq. 2; Weijers et al., 2007) indices were determined from the following equations:

\[
MBT' = \frac{[Ia + Ib + Ic]}{[IIIa] + [IIa + IIb + IIc] + [Ia + Ib + Ic]} \tag{1}
\]

\[
CBT = -\log\left(\frac{[IIb] + [Ib]}{[IIa] + [Ia]}\right) \tag{2}
\]

Roman numerals refer to the structures in the Supplementary Figure.

Based on triplicate injections, the maximal analytical error for the different indices was: 0.09 for MBT’ and 0.03 for CBT.
MAAT was estimated from the global soil calibration developed by Peterse et al., (2012; Eq. 3):

\[ \text{MAAT} = 0.81 - 5.67 \times \text{CBT} + 31.0 \times \text{MBT'} \] (3)

2.5. Estimation of the H isotopic composition of precipitation

To characterize the H isotope composition of precipitation ($\delta^2H_p$) at the studied sites, results from previous publications were gathered (Rieti-Shati et al., 2010; Nivet et al., 2015; Zech et al., 2015). Due to the limited number of instrumental data, $\delta^2H_p$ was also estimated with the Online Isotopes in Precipitation Calculator (OIPC; Bowen, 2016; Bowen and Revenaugh, 2003). The OIPC model was developed to allow point estimation of $\delta^2H_p$. It is based on a spatial interpolation from the 340 Global Network for Isotope in Precipitation (GNIP) station database. This interpolation includes the latitude and altitude effects on the isotopic composition of precipitation but in some regions, including East Africa, it is limited by additional sources of uncertainty. In East Africa, the major source of uncertainty is the small number of GNIP stations which lowers the dataset resolution (Bowen and Revenaugh, 2003; West et al., 2004) while the $\delta^2H_p$ variability is there especially high (due to the intertropical context and the orographic complexity). In addition, Bowen and Wilkinson (2002) pointed out 2 high altitude stations (Addis-Abeba and Entebbe) where the measured isotopic composition of precipitation was anomalously enriched in heavy isotopes, leading to an increased uncertainty in the prediction of $\delta^2H_p$ in this region. For the estimations along the 3 studied mountains, the 95% confidence level of the model varied from 3-4‰ at low altitudes to 6‰ at higher altitudes.
3. Results

3.1. $\delta^2$Hp and $\delta^2$Hwax along the altitudinal transects at Mt. Kenya and Mt. Rungwe

The $\delta^2$H$_p$ values along Mts. Kenya, Rungwe and Kilimanjaro obtained using the OIPC (the Online Isotopes in Precipitation Calculator; Bowen, 2016; Bowen and Revenaugh, 2003; Fig. 2) span from -42‰ at 3270 m.a.s.l. to -23‰ at 1900 m.a.s.l. along Mt. Kenya and from -49‰ at 2800 m.a.s.l. to -16‰ at 520 m.a.s.l. along Mt. Rungwe and from -45‰ at 3245 m.a.s.l. to -23‰ at 1727 m.a.s.l. along Mt. Kilimanjaro.

$n$-Alkanes were analysed in 20 soil samples collected between 1900 to 3160 m along Mt. Kenya and in 40 soil samples collected between 500 and 2800 m along Mt. Rungwe. The distribution parameters of these compounds (chain length range, C$_n$ range; average chain length, ACL; carbon preference index, CPI; cf. Supplementary Table 1) do not show any statistically relevant correlation with altitude. Along the two transects, long chain $n$-alkanes with odd-over-even predominance were the most abundant, as reflected by overall high ACL (28 ± 2; Suppl. Table 1) and CPI values (between 3 and 18; Suppl. Table 1). These results indicate that $n$-alkanes present in the soils originate predominantly from higher plants. The $\delta^2$H values are comprised between -109‰ and -177‰ (mean -143‰) at Mt. Rungwe, and between -116‰ and -167‰ at Mt. Kenya (mean -141‰; Suppl. Table 1). The weighted mean $\delta^2$H$_{wax}$ of the long chain $n$-alkanes (C$_{27}$, C$_{29}$, C$_{31}$) varied between -166‰ and -125‰ (Table 1) along Mt. Rungwe and between -158‰ and -119‰ along the slope at Mt. Kenya.
3.2. Br GDGT-derived mean annual air temperature (MAAT) along the altitudinal transects at Mts. Rungwe and Kenya

Br GDGTs were analysed along Mt. Kenya in the same soil samples as those analysed for \(n\)-alkanes (\(n=20\)). Br GDGT proxies and corresponding temperature estimates were previously determined in 20 surface soils collected at Mt. Rungwe in 2012 (Coffinet et al., 2014). This dataset was extended in the present study by the analysis of br GDGTs in 16 additional soil samples (same sample set as for the \(n\)-alkane analysis except 3 of them which were not analysed, see details in Table 1) collected along Mt. Rungwe. The distribution of br GDGTs was similar in soils collected in 2012 and 2014, as shown by the comparable ranges of MBT' and CBT values in these samples (cf. Suppl. Table 2).

Br GDGT-derived MAATs were estimated using the global soil calibration (Peterse et al., 2012) and varied from 9.3 °C at 3270 m.a.s.l. to 16.9 °C at 1900 m.a.s.l. along Mt. Kenya and from 12.2 °C at 2055 m.a.s.l. to 22.5 °C at 529 m.a.s.l. (Table 1).

4. Discussion

4.1. Variation of \(\delta^2\)H of \(n\)-alkanes in East Africa

In East Africa, the altitude effect on the hydrogen isotopic ratio of precipitation (\(\delta^2\)H\(_p\)) was reported along Mt. Kilimanjaro above 2000 m.a.s.l. (1.4‰/100 m) while it tends to be much weaker at lower altitudes (Zech et al., 2015 and Fig. 2). As Gonfiantini et al. (2001) observed at Mt. Cameroon (Cameroon), the altitudinal gradient in the \(\delta^2\)H\(_p\) seems to increase with altitude. Along Mt. Rungwe, the establishment of a long term...
monitoring of the isotopic composition of precipitation is ongoing (Nivet et al., 2015). Preliminary data indicate values ranging from \(-16.9‰\) at 1720 m.a.s.l. to \(-12.9‰\) at 920 m.a.s.l. and \(-11.3‰\) at 540 m.a.s.l. (Fig. 2) but more data are needed at higher altitudes to compare with Mts. Kilimanjaro and Cameroon trends. Along Mt. Kenya, Rieti-Shati et al. (2000) suggested the altitude effect to be absent based on precipitation events collected between 3000 and 4000 m.a.s.l. and groundwater collection above 4500 m.a.s.l. However, this assumption is based on a very limited dataset from high altitude sampling sites on the western side of the mountain whereas sampling for the present study was performed on the North-East slope of Mt. Kenya. Long-term monitoring of precipitation along a wide elevation range of this slope side at Mt. Kenya is needed to precisely assess the variation of its isotopic composition.

Because of this limited number of measured isotopic values of precipitation along the studied mountains, \(\delta^2H_p\) had to be estimated using the OIPC (the Online Isotopes in Precipitation Calculator; Bowen, 2016; Bowen and Revenaugh, 2003; Fig. 2). A \(\delta^2H\)-depletion lapse rate of 1.5 \%/100 m was computed for Mts. Rungwe and Kenya and of 1.4 \%/100 m for Mt. Kilimanjaro, similar to the one measured by Zech et al. (2015) above 2000 m.a.s.l. (Fig. 2). Nevertheless, along the latter, the OIPC data were observed to be shifted from the measured ones, particularly at higher altitudes, towards more depleted values and to a higher extent than the 95% confidence level estimated by the model (ca. 11‰ difference; Fig. 2). Such a shift was already observed and discussed in Kenya by Soderberg et al. (2013) and is likely due to the low number of GNIP stations whilst the rain composition exhibits a high spatial variability in the region. Therefore the absolute values derived from the OIPC must be treated with caution. However, they
should depict the likely trend of $\delta^2$H$_p$ related to the altitude effect and allow comparison between the three studied sites. Notably, the $\delta^2$H$_p$ varies from one mountain to another (Fig. 2). At a given altitude, 870 m.a.s.l. for example, $\delta^2$H$_p$ equals -22‰, -12‰, -8‰ along Mts. Rungwe, Kilimanjaro and Kenya, respectively. More specifically, the more northern the latitude, the more enriched the $\delta^2$H$_p$. This illustrates that, in addition to altitude, a latitudinal effect is also likely to impact the $\delta^2$H$_p$ distribution in East Africa, as previously noted at the global scale by Dansgaard (1964). No calibration of $\delta^2$H$_p$ with altitude could thus be deduced at the regional, East African, scale and the altitudinal effect in $\delta^2$H$_p$ could only be tracked at the mountain scale. Consequently, in the following, the ability of $\delta^2$H of n-alkanes ($\delta^2$H$_{\text{wax}}$) to track the altitudinal effect on $\delta^2$H$_p$ was solely investigated at the mountain scale for each study site. The concentration-weighted mean values of $\delta^2$H C$_{27}$ – C$_{31}$ alkanes ($\delta^2$H$_{\text{wax}}$, Table 1) were plotted against altitude for Mt. Kenya and Mt. Rungwe (Fig. 3A-B). A statistically significant, though scattered, $^2$H-depletion trend was observed along Mt. Kenya (-1.2‰/100 m; Fig. 3A; $p < 0.05$) close to the gradient observed for precipitation along Mt. Kilimanjaro (-1.4‰/100 m, Fig. 2). This result indirectly suggests the existence of an altitude effect in $\delta^2$H$_p$ along Mt. Kenya, unlike what was previously reported by Rieti-Shati et al. (2000). The $\delta^2$H$_{\text{wax}}$ values along Mt. Kenya support the hypothesis that n-alkanes are able to record the altitude effect in their $^2$H/$^1$H ratio, consistent with evidence from several other mountain systems in Asia (e.g. Jia et al., 2008; Bai et al., 2015) and New Zealand (Zhuang et al., 2015). In contrast, no trend was noticed at Mt. Rungwe (Fig. 3B, $p > 0.05$), as previously observed along Mt. Kilimanjaro (Peterse et al., 2009; Zech et al., 2015).
For these two mountains (Rungwe and Kilimanjaro), we suggest that the altitude effect observed in the precipitation may have been overprinted during the biosynthesis of $n$-alkanes and/or their diagenetic reworking in the soil. As reviewed by Sachse et al. (2012), lipid biosynthesis comprises several steps where $^{2}{\text{H}}/^{1}{\text{H}}$ fractionation can occur. The magnitude of fractionation on the end-product $\delta^{2}{\text{H}}_{\text{wax}}$ signal is still poorly constrained for most plant species. Notably, Sachse et al. (2012) highlighted several parameters that could have a high impact on the $\delta^{2}{\text{H}}_{\text{wax}}$ fractionation, such as vegetation changes, deposition processes and leaf physiology. Several studies pointed out large variability in the leaf-derived $\delta^{2}{\text{H}}_{\text{wax}}$ of different species within a same site (e.g. Chikaraishi and Naraoka, 2007; Pedentchouk et al., 2008). Thus, the important vegetation changes with altitude documented along Mts. Kilimanjaro and Rungwe (Bremond et al., 2008; Williamson et al., 2014) could have influenced the $\delta^{2}{\text{H}}_{\text{wax}}$ signal, leading to an overprinting of the altitude effect on the $\delta^{2}{\text{H}}$ of the precipitation. Moreover, Zech et al. (2015) postulated that along Mt. Kilimanjaro the altitudinal effect should be outcompeted by the increasing evaporative $^{2}{\text{H}}$-enrichment of the leaf water due to changes in humidity with increasing altitude. The impact of these potential additional effects could be enhanced in East Africa, where the altitude effects on $\delta^{2}{\text{H}}_{\text{p}}$ (Fig. 2) are in the lower range of the gradients measured across the world (between -1 and -4‰/100 m, Araguás-Araguás et al., 2000).

The results from this study highlight the complexity of the $^{2}{\text{H}}$ isotopic signal recorded in $n$-alkanes from East African soils. The altitude effect on $\delta^{2}{\text{H}}_{\text{p}}$ was recorded in the $\delta^{2}{\text{H}}_{\text{wax}}$ signal at only one altitudinal transect (Mt. Kenya). This suggests that the use of $\delta^{2}{\text{H}}_{\text{wax}}$ as a (paleo) elevation proxy might be site-dependent. This study also points to
the competitive impact of different hydroclimatic and biogeochemical factors on the soil $\delta^2$H$_{wax}$ record. Unfortunately the lack of extensive environmental monitoring in these remote locations prevented us from determining which of these factors are overprinting the $\delta^2$H$_{wax}$ signal at the other two mountains. Notably, more instrumental data are needed to improve the estimation of the $\delta^2$H$_{p}$ in East Africa. These observations probably also hold for other mountainous regions across the world and should therefore be taken into consideration in regional scale (paleo) elevation studies. The application of $\delta^2$H$_{wax}$ for (paleo) elevation reconstructions must therefore be limited to the mountain scale and should always be accompanied by detailed surveys of the environmental setting of the study site.

4.2. East African regional br GDGT calibration

Linear altitudinal gradients of measured mean annual air temperatures (MAAT) were observed along all the investigated East African mountains: 0.56 °C/100 m in Mt. Kilimanjaro (Tanzania, Sinninghe Damsté et al., 2008), 0.53 °C/100 m in Mt. Rwenzori (Uganda, Loomis et al., 2011), 0.73 °C/100 m in Mt. Rungwe (Tanzania, Coffinet et al., 2014, Williamson et al., 2014) and 0.63 °C/100 m in Mt. Kenya (Kenya, Camberlin et al., 2014; Kenya Meteorological Department, 1984; Kenya Meteorological Department; Smith, 1993). The goal of this study was to investigate whether it is possible to establish a regional East African framework for the use of soil derived-br GDGTs as a paleo-thermometer. Thus, the measured MAAT data from all the local East African transects mentioned above were combined to calculate a regional temperature lapse rate (Fig. 4). This rate, determined as 0.65 °C/100 m, with 97% of the MAAT variance being
explained by altitudinal variations (Fig. 4), is similar to the one commonly used in low
precision studies (Rolland, 2003; Grab, 2013 and references therein) and will allow us to
assess the effect of temperature changes on br GDGT distribution at the regional scale.

In addition to Mts. Kenya and Rungwe investigated in the present study, br
GDGT distribution was previously investigated along two additional East African
mountains, Mt. Rwenzi (Uganda; Loomis et al., 2011) and Mt. Kilimanjaro (Tanzania,
Sinninghe Damsté et al., 2008). Br GDGT-derived MAATs were estimated using the
global soil calibration (Peterse et al., 2012; Weijers et al., 2007) and were found to
successfully record the decrease in MAAT with altitude along the slopes of these two
previously studied mountains. However, the soils sampled at the highest elevations in Mt.
Rwenzi exhibited a significant cold bias (Loomis et al., 2011). The authors suggested
that the water saturation of these soils may additionally impact the br GDGT distribution.
An impact of extreme soil water content (either aridity or saturation) on br GDGT
distribution and corresponding temperature estimates has indeed been reported in several
publications (e.g. Huguet et al., 2010 Dirghangi et al., 2013; Menges et al. 2014; Dang et
al., 2016).

Br GDGT-derived MAATs calculated using the soil calibration by Peterse et al.
(2012) were also shown to decrease linearly with altitude along Mts. Rungwe and Kenya
(R² = 0.79 and 0.66 respectively; figures not shown). Combined together, these four
studies highlight the robustness of br GDGTs as a paleo-temperature proxy, at least for
East Africa (MAAT lapse-rate = 0.4 °C/100 m, R² = 0.63; Fig. 5C). Despite this positive
assessment, the application of the global soil calibration still leads to a substantial
Combination of the new and previously published (Sinninghe Damsté et al., 2008; Loomis et al., 2011; Coffinet et al., 2014) data from East Africa, leads to a br GDGT dataset from in total 105 soils. Because of the potential additional impact of water saturation on brGDGT distribution and thus associated temperature estimates, the high elevation samples from Loomis et al. (2011) were not used in this dataset. Based on this integrated sample set, a least square multiple linear regression was performed between br GDGT distribution (MBT’ and CBT indices) and the available MAAT for the four sites (Mt. Kenya, Rwenzori, Kilimanjaro and Rungwe). The following equation was obtained:

\[
MAAT = -8.76 \times CBT + 24.24 \times MBT' + 9.60 \quad (R^2 = 0.77, \text{RMSE} = 2.4 ^\circ C) \quad (4)
\]

This regional soil calibration (Fig. 5B) strongly improves both the R² and RMSE of br GDGT-reconstructed MAAT over the global soil calibration derived from globally distributed soils (Fig. 5A, Peterse et al., 2012). The new East African calibration produces robust quantitative temperatures from br GDGT distributions in soils as it takes into account the regional specificities in soil water content, soil type, biome type, all of which that could potentially impact br GDGT abundance and distribution (e.g. Dirghangi et al., 2013; Menges et al., 2014). This highlights the necessity for regional determinations of the relationship between temperature and br GDGT distribution in order to improve past-temperature estimates. But it also points to the question of defining coherent regions over the globe with a relevant scale.

The East African soil calibration developed in this study was applied to the MAAT reconstruction in modern soils along all four altitudinal transects (Fig. 5D). The
resultant br GDGT-derived MAAT lapse rate (0.52 °C/100 m; Fig. 5D) is closer to the measured one (0.65 °C/100 m; Fig. 5D) than when using the global soil calibration (0.41 °C/100 m; 5C), but still underestimates the actual lapse rate by ca. 20 %. This points to the unsuitability of using br GDGTs alone to reconstruct past elevation changes. Independently of that, the correlation between MAAT estimates and altitude is higher when using the new regional soil calibration (R² = 0.80; Fig. 5D) than the global one (R² = 0.63; Fig. 5C), and closer to the correlation found between instrumental MAAT and altitude (R² = 0.97; Fig. 4). Therefore, the consistency and increase in quality of this new regional calibration for temperature reconstruction calls for its wider application in paleosol-based paleo-climatic reconstructions in East Africa. So far, in this region, br GDGT-derived proxies have only been used in lacustrine sedimentary records (e.g. Tierney et al., 2010; Sinninghe Damsté et al., 2012). This regional but valuable climatic information can also be deduced from paleosol sequences (e.g. Hatté et al., 2001; Gocke et al., 2014), which are abundant in East Africa due to the high rate of volcanic activity (e.g. in the Rungwe volcanic province, Fontijn et al., 2010). First applications of br GDGTs in such soil settings from across the world have revealed promising results (e.g. Peterse et al., 2011; Zech et al., 2012).

5. Conclusions

δ²H_wax and br GDGT distributions were determined in 60 surface soils collected along altitudinal transects of two East African mountains (Mt. Rungwe in Tanzania and Mt. Kenya in Kenya). The obtained values were combined with data from altitudinal gradients of previous studies in the region to assess the applicability of integrated δ²H_wax
and br GDGTs data sets as coupled paleo-topography and paleo-temperature proxies, respectively, in East Africa. Variations in $\delta^2$H$_{wax}$ do not systematically document altitudinal changes, with only one out of the three investigated mountains showing a positive relationship – even though the altitude effect was present in the $\delta^2$H of precipitation. At the regional (East African) scale, coupling of estimated and observed $\delta^2$H$_p$ data highlights their spatial heterogeneity. The use of $\delta^2$H$_{wax}$ as a paleo-elevation proxy must therefore be restricted to site (mountain)-specific studies. In contrast, br GDGT-derived MAAT reliably track measured MAAT gradients along the four studied mountains (Mts Rungwe, Kenya, Kilimanjaro and Rwenzori). The large dataset of both measured and br GDGT-derived MAAT in the study area enabled to establish a new regional East African soil calibration between br GDGT distribution and MAAT. This new calibration improves the accuracy of MAAT reconstruction for the studied region, in comparison to other global soil calibrations, and highlights the potential of br GDGTs as paleo-thermometers in recent and ancient East African soils.

Acknowledgements

The authors would like to thank the RESON (Rungwe Environmental Science Observatory Network) and those who help them during field trips, notably Stephen Kajula, Winne Mosena, Matokeo Arbogast, Stephen Warui, Marcel Hale and the inhabitants of Masoko. Paul Donohoe and Bernard Bowler are warmly acknowledged for their technical support at Newcastle University. The authors are indebted to Dr. Pierre Camberlin (University of Bourgogne, France) who shared his temperature dataset from Mt. Kenya. This research benefited from a travel grant awarded by the EAOG and a PhD
scholarship from UPMC to S. Coffinet as well as support from the EC2CO program (CNRS/INSU) to A. Huguet. The work under permit NCST/RCD/17/013/02 on Mt. Kenya (C. Omuombo) was supported from French AIRD and Campus France through the French embassy in Nairobi.
