Abstract

We investigate well-accepted formulations describing charge transport in composite cathodes of batteries. Our upscaling of carefully selected microscopic equations shows three main features:

(i) a novel set of six equations equipped with nine effective parameters which systematically couple the microscale to the macroscale;

(ii) the coupling of transport and flow equations allows to account for three scales: pore scale, Darcy scale, and macroscale;

(iii) the upscaled equations take phase separation during Li-intercalation into account as well as specific particle configurations.

The wide range of applications and interest in energy storage devices make these results a promising tool to study the influence of the microstructure on current-voltage characteristics and to optimize cathode designs.

Keywords: batteries, homogenization, current-voltage curves, lithium intercalation, phase separation, Butler-Volmer reactions

1 Introduction

We look at basic and widely accepted equations describing charge transport and reactions in composite cathode materials of energy storage systems such as Li-batteries. The main goal of this article is to systematically and reliably derive effective macroscopic equations that account for characteristic material properties such as geometric features of interfaces and material phases as well as electric and ionic conductivities and reaction rates. In particular, the subsequent mathematical modelling shall help to gain a deeper understanding into how material properties influence experimentally measured current-voltage characteristics. With the introduction of LiFePO$_4$ as a promising cathode material in 1997, strong improvements in charging and discharging rates as...
well as in safety have helped to make phosphates a promising battery material \[22\]. A crucial role for the charging and discharging rate plays the so-called Li-intercalation in which Li-ions enter into crystalline phosphate particles of the composite cathode. During this process, the phosphate material can phase separate into a Li-rich phase and a Li-poor phase for which a first modelling seems to be \[21\]. Previous formulations describe the intercalation by a shrinking core using radial diffusion \[14\]. Crystalline intercalation compounds show a topotactic transition, i.e., the compound may change its structure due to gain or loss of material (which is Li here). Recent research suggests that a change in structure/phase separation can be suppressed in LiFePO$_4$ nanoparticles, e.g. \[4\]. Suppression can occur in equilibrium \[30\], but when a current flows \[28\], non-idealities are enhanced and hence the suppression seems even more likely. This leads immediately to the important and interesting question what influence can the micro-geometry have on the appearance of phase separation in these composite cathodes and on the current-voltage characteristics. For instance, it is possible that different parts of the composite cathode are in a different state and hence phase separation can be expected to be a very local property over time. In order to better understand the key properties of composite cathodes for optimizing design and safety, systematic mathematical and thermodynamic modelling will play a crucial role towards a reliable, effective macroscopic description of intercalation kinetics of Li$^+$-ions into solid particles such as FePO$_4$.

Existing porous electrode theory for batteries relies on intuitive, formal, or ad hoc averaging strategies based on integrating the equations directly over a representative volume element \[4, 19, 48\]. This kind of intuitive averaging seems to take dominant transport characteristics such as porosity and surface area into account but generally neglects more subtle geometric features such as pore shape and properties that go beyond porosity and tortuosity characterisations. Currently, it is still an open question how to rigorously justify the volume averaging approach. Often, these methods are refined with physically derived corrections to transport coefficients. Famous porous media corrections to transport parameters are the so-called Bruggeman relation \[7\], i.e., the diffusion coefficient $D_p$ of the pore phase is obtained by multiplying the free space diffusion parameter $D_f$ by the factor $p^{3/2}$ where $p$ is the porosity. More refined relations also take the tortuosity into account \[49\], i.e., $D_p = 1/\tau D_f$. The parameter $\tau$ is the tortuosity defined as the quotient $\tau := L_a/L_s$ where $L_a$ is the length of the actual transport path through the pore and $L_s$ is the shortest distance connecting entrance and exit of a reference pore. There is increasing interest in the context of ionic transport to systematically derive upscaled/homogenized equations \[2, 25, 38, 42, 43, 45\]. For fuel cell and battery systems recent upscaling results are \[20, 26, 39, 46\] for instance. A summary of work closely related to the results presented in this article is given in Tab. \[1\]. Due to increasing interest and number of publications, we do not claim this table to be complete.

Besides a wide interest in thermodynamics and materials science, the highly heterogeneous and multiphase character of composite cathodes requires a systematic and reliable derivation of effective macroscopic transport equations taking physically observed principles as well as geometric features of the microscale into account while still allowing for feasible and efficient computational schemes. The homogenization of charge transport equations in cathodes is the main goal of this article. The basic idea in homogenization is to account for at least one smaller length scale $\ell \ll L$, the so-called microscale $y = \ell \xi L \in Y \subset \mathbb{R}^d$, which takes geometric features such as pore shape or changing material properties such as electric permittivity/conductivity into account. The parameter $L$ is the macroscale (e.g. length of the composite cathode) such that $\ell = \frac{\epsilon}{L}$ represents the material’s heterogeneity. The microscale is identified by a periodic reference cell (periodic homogenization). Homogenized equations can then be obtained by applying a so-called asymptotic
Table 1: Summary of derivations of effective macroscopic equations for battery systems with Li-intercalation. The fact that the majority of work relies on volume averaging can be in part motivated by the fact that this intuitive method is more formal as it does not require rigorous existence and uniqueness results in the derivation like the asymptotic two-scale expansion applied here. Due to an increasingly growing literature on Li-battery modelling over the last decade, we do not claim this list to be complete.

multiscale expansion of the form
\[ u^\epsilon(x) = u(x,y) = u_0(x,y) + \epsilon u_1(x,y) + \epsilon^2 u_2(x,y) + \cdots. \]

Then well-posedness theory allows us to identify the equations for \( u_0 \) and \( u_1 \) which represent the relevant terms in the upscaled/homogenized problem. This is a well-accepted methodology by now [10, 12, 23, 31].

We describe the composite cathode of lithium ion batteries together with available charge transport equations in Section 2. Then, we formulate the microscopic composite cathode model which we will subsequently upscale/homogenize and which fully resolves the different phases in Section 2.2. Based on well accepted charge transport models, we present the homogenized/upscaled charge transport equations for composite cathode materials in Section 3. A derivation based on the asymptotic two-scale expansion follows then in Section 3.1.

2 Microscopic composite cathode formulation

We consider a composite cathode which consists of solid intercalation particles \( Y_s \subset Y := [0,1]^d \), \( d \in \mathbb{N} \) dimension of space, and a polymer solution \( Y_p \subset Y \) which together define a characteristic reference cell \( Y := Y_p \cup Y_s \), see Fig. 1 (Left). Moreover, the particles \( Y_s \) are connected via thin carbon black pathways allowing for electron transport. We state the basic equations that account for charge transport in a composite as defined in the reference cell \( Y \). We refer the reader not interested in an overview on available physical models directly to Section 2.2 where we formulate the microscopic starting point of our upscaling/homogenization derivation.
2.1 Basic physical processes and models

Before we look at the upscaling/homogenization of the composite cathode, we introduce models available in the literature to describe charge transport.

(S) Li-Intercalation compound/particles (solid matrix):
The intercalation particles show two different transport characteristics, i.e., electron transport and Li-intercalation into an electrochemical solid (subject to constraints such as charge and mass conservation, see [19] for instance.) The general atomic transport/diffusion mechanisms through solids are either by interstitial diffusion (defects in lattice where atoms assume a normally unoccupied site), vacancy diffusion (driven by thermal energy of atomic vibrations), or via impurities (inter-diffusion driven by concentration gradients). Interstitial diffusion is generally faster than vacancy diffusion due to the higher number of interstitial sites and the weaker bonding of interstitials to neighbouring atoms. Since Li resides in interstitial sites, crystalline intercalation hosts such as FePO$_4$ are favourable for battery applications. We focus here on topotactic compounds, that means, hosts/particles that may change its structure due to gain or loss of material. As a consequence, the local Li concentration can serve as a field variable which differs between a Li-rich and a Li-poor phase separated by a diffuse interface.

(i) Li-intercalation: The thermodynamics of phase separation can be systematically described by phase field models [4, 8, 18, 21, 36] which rely on a thermodynamic free energy functional

$$F_r(c_s) = n_v \int_{D_s} f_r(c_s) + \tilde{\lambda} (\nabla c_s)^2 \, dx,$$

(2.1)

where $f$ is the homogeneous free energy of a regular solution, that is,

$$f_r(c_s) = \omega c_s (1 - c_s) + k_B T (c_s \log c_s + (1 - c_s) \log (1 - c_s)).$$

(2.2)

The parameter $\omega$ in (2.2) is an effective interaction energy between a Li interstitial site and its neighbouring (Li-free) sites. The parameter $\lambda$, which accounts for the strength of penalisation of concentration gradients, is proportional to the interfacial width and assumes in the case of LiFePO$_4$ as intercalation material the following form,

$$\tilde{\lambda} = a^2 \omega / 6,$$

(2.3)

where $\omega = 59$ meV is the nearest neighbour interaction energy and $a = 2.5\,\text{Å}$ the nearest neighbour distance. Using also $n_v = 8.396 \times 10^{28} [/m^3]$ then leads to $\lambda = n_v \tilde{\lambda} = 2.48 \times 10^{-11} \, \text{J/m}$ as in [21].

Taking a mass conserving gradient flow, i.e., computing the variational derivative with respect to test functions $v \in H^1(D_s)$, we obtain up to boundary terms

$$\partial_t c_s = - \text{div} \left( \tilde{\mathcal{M}} \nabla \left( \nabla^{H^1} c_s F_r(c_s) \right) \right),$$

(2.4)

where the derivative $\nabla^{H^1}$ represents the Gâteaux derivative. That means, for all $v \in H^1(D_s)$ we compute

$$\frac{\delta^v F_r(c_s)}{\delta^v c_s} = \lim_{\theta \to 0} \frac{F_r(c_s + \theta v) - F_r(c_s)}{\theta} = \left( (f_r'(c_s) - \lambda \Delta c_s), v \right) = \left( \nabla^L^{H^1} \tilde{\mathcal{M}} c_s F_r(c_s), v \right),$$

(2.5)

where the last equality identifies $\nabla^L^{H^1} F_r(c_s)$ by Riesz’s theorem. In the same way we can apply Riesz’s theorem with respect to the semi-inner product $\left( \tilde{\mathcal{M}} \nabla u, \nabla v \right)_{H^1}$ for $u, v \in H^1(D_s)$ and a
symmetric positive definite tensor $\hat{M}$ to define $\nabla_{c_s}^H F_r(c_s)$ under homogeneous Neumann boundary conditions as follows
\[
\left( \nabla_{c_s}^H F_r(c_s), v \right) = \left( \hat{M} \nabla_{c_s}^L F_r(c_s), \nabla v \right) = \left( -\text{div} \left( \hat{M} \nabla_{c_s}^L F_r(c_s) \right), v \right).
\] (2.6)

Putting (2.12)–(2.6) together, leads with $f'_r(c_s) = \omega(1-2c_s)+k_B T \log \left( \frac{c_s}{1-c_s} \right)$ to the phase field equation for intercalation compounds
\[
\partial_t c_s = \text{div} \left( \hat{M} \nabla \left( f'_r(c_s) - \lambda \Delta c_s \right) \right),
\] (2.7)

where the mobility tensor $\hat{M}$ is often chosen as a constant $M_s$ since generally it is difficult to trace back the irreversible behaviour to the underlying frictional processes after coarse graining. A state equation with concentration dependent mobility is suggested in [21], i.e., $\hat{M} = c_s(1-c_s)M_0$ where $M_0$ is a constant.

(ii) Electron transport: We describe charge transport in the solid matrix by the current
\[
i_s = -\sigma_s \nabla \psi_s,
\] (2.8)

where $\sigma_s$ is the conductivity of the solid intercalation phase $D_s$ and $\psi_s$ is the electric potential in $D_s$. Equation (2.8) is widely used in the literature, e.g. [48].

(E) Electrolyte/separator:
A large part of the electrochemical literature is dedicated to transport equations for binary electrolytes. These denote solutions containing a single binary salt of the form $X_1X_2$ plus a solvent (generally polymer in Li-batteries) where $X_1^+$ and $X_2^-$ represent a cation and an anion, respectively. Electrolytes $X_1X_2$ that dissociate into an equal number of cations $\nu_+$ and anions $\nu_-$ are called symmetric. Subsequently, we present four different formulations (E1)–(E4) for binary electrolytes.

(E1) Dilute solution theory: charge transport by Poisson-Nernst-Planck (PNP). There is a wide range of different modelling approaches as well as analytical studies of charge transport formulations such as [17, 24, 27, 29, 40, 41, 45]. Recently, the PNP system has been modified to describe electrolytes beyond the dilute approximation in [15], see also Remark 2.1 below. The widely used and well-accepted Nernst-Planck formulation allows us to take the densities $c_i$ of each species $i$ in the solution into account. Since we consider a polymer electrolyte as a solution, we have a neutral ($z_0=0$) density $c_0$ for the polymer solvent, the cation density $c_+ = c_1$ of lithium ions $X_1^+$, and the anion density $c_- = c_2$ of negative salt ion $X_2^-$. The following classical and well-accepted description is based on the PNP system,

(PNP) \[
\begin{aligned}
\partial_t c_i + \mathbf{u} \cdot \nabla c_i &= \text{div} \left( D_i \nabla c_i + \varepsilon z_i c_i M_i \nabla \psi \right), & \text{for } i = 0, 1, 2,
\end{aligned}
\] (2.9)

where $M_i$, $D_i$, and $z_i$ are the diffusion, mobility, and charge number of species $i$, respectively. The parameter $\varepsilon$ is the electric permittivity of the electrolyte and $e$ denotes the elementary charge. The fluid velocity $\mathbf{u}$ is the solution of the incompressible Navier-Stokes (iNS) equations extended by a Coulomb force term on the right-hand side [24, 40, 41], i.e.,

(iNS) \[
\begin{aligned}
\partial_t \mathbf{u} + \mathbf{u} \cdot \nabla \mathbf{u} - \nabla p &= -\varepsilon \sum_{i=0}^2 z_i c_i \nabla \psi, \\
\text{div} \mathbf{u} &= 0.
\end{aligned}
\] (2.10)
In the context of the dilute solution theory, see Remark 2.1 below for more details, one does not use the flux of the solvent, i.e., \( i = 0 \) in (2.9), but instead the solvent is solely described by the momentum equation (2.10). For simplicity, we will subsequently denote the cation density by \( c_+ \), the anion density by \( c_- \).

(E2) **Binary electrolyte [48]**. Since bulk electroneutrality is a widely confirmed characteristic property of solutions, we make the frequent assumption of an electrically neutral solution, i.e.,

\[
\sum_i z_ic_i = 0. \tag{2.11}
\]

We note that the neutrality assumption (2.11) is violated in interfacial regions (e.g. near electrodes) where thin electrical double layers (EDL) appear. Under electroneutrality, the concentration of the electrolyte is consistently defined by

\[
c := \frac{c_+}{\nu_+} = \frac{c_-}{\nu_-}. \tag{2.12}
\]

Moreover, we assume constant mobilities and diffusion coefficients. Applying the fluxes \( j_i, i = 1, 2 \), from the Nernst-Planck setting (2.9) leads to

\[
\begin{aligned}
\partial_t c + u \cdot \nabla c &= D \Delta c, \\
(z_+M_+ - z_-M_-)F \text{div}(c\nabla \psi) + (D_+ - D_-) \Delta c &= 0,
\end{aligned} \tag{2.13}
\]

where \( D = \frac{z_+M_+D_+ - z_-M_-D_-}{z_+M_+ - z_-M_-} \).

Remark 2.1 (Validity) The dilute solution theory is recommended as a general formulation since it is widely used in the electrochemical literature and at the same time it accounts for the essential physical processes involved without very complicated/less accessible ingredients [48, p.274]. But one should be aware that the fluxes defined in (2.9) break down because electro-migration and diffusion are not consistently defined with respect to an average velocity \( u \) of the fluid. A way out of this is a so-called dilute solution where one does not apply (2.9) to the solvent, i.e., \( i = 0 \), but solely to the ionic species and where one attributes the fluid velocity \( u \) to the velocity of the solvent. Recently, the authors of [15] have carefully specified the fluid velocity \( u \) in order to overcome the above noted difficulty.

(E3) **Concentrated solution.** We state a charge transport model for a polymer electrolyte as proposed in [14] for composite cathodes. This transport formulation relies on experimentally measurable quantities such as the transference number. We still assume that the polymer electrolyte is a solution of a binary salt and a solvent. For a Li-polymer insertion cell the solution is for instance a binary salt LiX and the solvent a polymer. Taking the polymer as a reference species, the following material balance on the lithium salt electrolyte \( c = c_i/\nu_i \),

\[
\partial_t c = \text{div} \left( D(c) \left( 1 - \frac{d(ln c_0)}{d(ln c)} \right) \nabla c \right) - \frac{\mathbf{i}_p \cdot \nabla t^0_+(c)}{z_+\nu_+F}, \tag{2.14}
\]

where \( t_j = \frac{z_j^2M_jc_j}{\sum_i z_i^2M_ic_i} \) is the experimentally obtained transference number which accounts for the current associated with species \( j \). In [14], the following fit to experimental data is employed

\[
t^0_+ = 0.0107907 + 1.48837 \times 10^{-4}c. \tag{2.15}
\]
Following again the concentrated solution theory [18] applied to lithium-polymer insertion cells in [14], the current $i_p$ in the polymer phase admits the following representation

$$i_p = -\kappa(c) \nabla \psi_p - \frac{\kappa(c)RT}{F} \left( 1 + \frac{\partial \ln f_\pm}{\partial \ln c} \right) \left( \frac{s_+}{n_+} + \frac{\theta_+(c)}{z_+} \right) \nabla \ln c,$$  \hspace{1cm} (2.16)

where the electric potential $\psi_p$ in the polymer phase is measured with a reference electrode, $\kappa = F \sum_i z_i^2 M_i c_i$ is the conductivity of the solution not accounting for concentration gradients. The variable $f_\pm$ is the activity coefficient of the salt and is only accounted for if data are available [14].

\textbf{(E4) Onsager-type equations away from equilibrium.} The subsequent charge transport formulation has been introduced in [16]. The concentration of lithium $c^+$ in the electrolyte phase is governed by the following system

$$\partial_t c^+ = \text{div} \left( k_{11}^+(c^+) \nabla c^+ + k_{12}^+ \nabla \psi \right) = 0,$$

$$0 = \text{div} \left( k_{21}^+(c^+) \nabla c^+ + k_{22}^+ \nabla \psi \right),$$

where the coefficients are defined for the ion conductivity $\kappa^+$ and ion diffusion coefficient $D^+$ by

$$k_{11}^+(c^+) = D^+ + \frac{RT (t_+)^2 \kappa^+}{c^+}, \quad k_{12}^+ = \kappa^+ \frac{t_+}{F},$$

$$k_{21}^+(c^+) = \frac{RT \kappa^+ t_+}{F}, \quad k_{22}^+ = \kappa^+.$$  \hspace{1cm} (2.18)

\textbf{Remark 2.2 (Comments to formulations (E1)-(E4))} The formulations (E1)-(E2) are widely used in theory and computational modelling whereas (E3) is generally used in experimental science in view of particular parameters that represent directly measurable quantities. The transport equations (E4) are interesting as they resemble in their stationary form the classical Onsager relations [34, 35].

\textbf{(I) Solid-electrolyte interphase:} The interfacial transition of Li from the polymer solution into the solid insertion compound is governed by the Butler-Volmer kinetics [3, 5]. Following Doyle et al. [14], the following reaction

$$\text{Li}^+ - \Theta_p + \Theta_s + e^- \rightleftharpoons \text{Li} - \Theta_s + \Theta_p,$$  \hspace{1cm} (2.19)

governs the Li insertion into the solid matrix. The variables $\Theta_p$ and $\Theta_s$ stand for the available sites in the polymer and the solid matrix (interstitial). For an overpotential $\eta := \psi_s - \psi$ between the solid ($\psi_s$) and the bulk electrolyte ($\psi$) and the voltage $U = U_2^\theta - U_\text{ref}^\theta + RT/F(\beta c_s + \zeta)$, the insertion process \textbf{(2.19)} induces the current

$$i = F k_{fb}(c_{pm} - c)^{\alpha_c} c^{\alpha_a} \left[ c_s \exp \left( \frac{\alpha_a F}{RT} (\eta - U) \right) - (c_{sm} - c_s) \exp \left( -\frac{\alpha_a F}{RT} (\eta - U) \right) \right],$$

\hspace{1cm} (2.20)

where $c_{sm}$ and $c_{pm}$ are the maximal densities in the solid and the polymer phase, respectively. The variable $\zeta$ is a constant expressing corrections to activity. We will set these parameters according to [14], i.e., $c_{sm} = 29000\text{mol/m}^3$, $c_{pm} = 3920\text{mol/m}^3$. Additionally, the transfer coefficients are $\alpha_a = \alpha_c 0.5$, and the reaction rate at the particle-electrolyte interface is $k_{fb} = 10^{-10}\text{m}^4/(\text{mol} \cdot \text{s})$. 
Figure 2: **Left:** A 2D periodic composite cathode \( D = D_p^e \cup D_s^e \) of characteristic length \( L \) with solid intercalation particles \( D_s^e \) surrounded by a polymer electrolyte solution. This black lines are electric conducting pathways in the form carbon black. This cell motivates a layer by layer assembly. We note that this figure can serve as a reference cell that represents a characteristic configuration of intercalation particles electrically connected in various ways via carbon black, and surrounded by polymer electrolyte. **Right:** A 3D sample reference cell of a possible cathode composed of FePO\(_4\) particles connected via carbon black particles (thin lines). Obviously, more complex cells can be used.

Hence, the intercalation current density (2.20) governs how the the Li\(^+\)-flux \( j_p = \hat{M}_p \nabla (c + z_c c \nabla \psi_p) \) from the polymer solution is related to the Li-flux \( j_s = \hat{M}_s \nabla (f'(c_s) - \lambda \Delta c_s) \) in the solid intercalation compound. Based on the interfacial reaction (2.19), we have the following boundary conditions on the interface,

\[
\begin{align*}
\text{(Interfacial kinetics)} \\
& \begin{cases} 
  i = -\frac{n_i}{s_i} j_p \cdot n & \text{on } \partial D_p, \\
  i = -j_s \cdot n & \text{on } \partial D_s, \\
  i = -\sigma_s \nabla \phi_s & \text{on } \partial D_s, 
\end{cases}
\end{align*}
\]

(2.21)

where \( n \) is the outward normal of the corresponding domains and the number of electrons is one, that is, \( n = 1 = s_i \), where \( s_i \) is the stochiometric parameter.

### 2.2 Microscopic equations for composite cathodes

Based on the previous Section 2.1, we can now state the microscopic system of equations describing charge transport in a periodically extended composite cathode, see Fig. 2. We distinguish two different microscales, that is, a reference pore scale of characteristic length \( l_p \) and a so-called Darcy scale of characteristic length \( l_D \). Herewith, mass transport is governed by the heterogeneity \( \epsilon_p = \frac{l_p}{L} \) of pores where \( l_p \) is the characteristic size of a reference particle configuration and \( L \) is the macroscopic length of the composite cathode. The microscopic formulation fully resolves the highly heterogeneous geometry of the composite cathode in which we have to account for three essential transport mechanisms: (1) Diffusive and electro-migrational transport in the polymer
solution
\[ D_p^\epsilon := \bigcup_{z \in \mathbb{Z}^d} \epsilon_p (Y_p + z) \cap D; \]

(2) Interstitial diffusion inside a solid intercalation compound
\[ D_s^\epsilon := \bigcup_{z \in \mathbb{Z}^d} \epsilon_p (Y_s + z) \cap D \]

(described by a mean field phase field equation); and (3) Reaction kinetics on the interface \( I_p := \partial D_p^\epsilon \cap \partial D_s^\epsilon \) given by the Butler-Volmer equations (2.20) which are imposed as boundary conditions.

The following equations fully describe the microscopic kinetic processes in the composite cathode and hence are indexed by the pore heterogeneity \( \epsilon_p \). Moreover, we allow for a further length scale \( l_D > l_p \), called Darcy scale, see Fig. [1] Right. This then leads to a so-called Darcy’s heterogeneity \( \epsilon_D := \frac{l_D}{L} \). We note that the subsequent results are valid for scenarios where the pore scale \( \epsilon_p \) differs from the Darcy scale \( \epsilon_D \), i.e., where \( \epsilon_p < \epsilon_D \). Hence, the scaling \( \epsilon_p < \epsilon_D \) enables us to account for a third scale via the momentum equation. Hence, fluid flow is considered on a perforated domain
\[ D_p^{\epsilon_D} := \bigcup_{z \in \mathbb{Z}^d} \epsilon_D (Y_D^p + z) \cap D \]

which is defined by a slightly larger representative volume element \( Y_D^p \) accounting for the Darcy scale \( l_D \). As the boundary conditions on \( \partial D \) do not have a direct influence in the upscaling inside the composite cathode \( D \), we do not state here how \( D \) interacts with external forces and systems as this can still be made precise at a later stage.

Due to confined material structure, one can expect a fast relaxation time for the flow as well as a small characteristic flow field. Therefore, the flow is governed by a small Reynolds number \( Re = \frac{\rho U_{ref} L}{\mu} \) (where \( \rho \) is the density of the fluid, \( U_{ref} \) is a reference velocity, \( \mu \) the dynamic viscosity, and \( L \) a characteristic length of the system) and hence instead of using the full time-dependent Navier-Stokes equations to define \( \mathbf{u}^{\epsilon_D} \), we can apply a quasi-stationary formulation based on Stokes equations, i.e.,
\[
\begin{align*}
-\epsilon_D^2 \mu \Delta \mathbf{u}^{\epsilon_D} + \nabla p^{\epsilon_D} &= \mathbf{f}^{\epsilon_D} := -e(z_+ c_+^{\epsilon_D} - z_- c_-^{\epsilon_D}) \nabla \psi^{\epsilon_D} \quad \text{in } D_p^{\epsilon_D}, \\
\text{div} \mathbf{u}^{\epsilon_D} &= 0 \quad \text{in } D_p^{\epsilon_D},
\end{align*}
\]

where \(-e(z_+ c_+^{\epsilon_D} - z_- c_-^{\epsilon_D}) \nabla \psi^{\epsilon_D}\) is a Coulomb driving force [24, 40, 41]. In the polymer electrolyte (binder), we have
\[
\begin{align*}
\partial_t c_+^{\epsilon_D} + \mathbf{u}^{\epsilon_D} \cdot \nabla c_+^{\epsilon_D} &= \text{div} \left( k_B TM_+ \left( \nabla c_+^{\epsilon_D} + \epsilon e z_+ c_+^{\epsilon_D} \nabla \psi^{\epsilon_D} \right) \right) \quad \text{in } D_p^{\epsilon_D}, \\
\partial_t c_-^{\epsilon_D} + \mathbf{u}^{\epsilon_D} \cdot \nabla c_-^{\epsilon_D} &= \text{div} \left( k_B TM_- \left( \nabla c_-^{\epsilon_D} - \epsilon e z_- c_-^{\epsilon_D} \nabla \psi^{\epsilon_D} \right) \right) \quad \text{in } D_p^{\epsilon_D}, \\
-\text{div}(\epsilon_p \nabla \psi^{\epsilon_D}) &= e(z_+ c_+^{\epsilon_D} - z_- c_-^{\epsilon_D}) \quad \text{in } D_p^{\epsilon_D},
\end{align*}
\]

where the parameter \( \epsilon_p \) denotes the electric permittivity of the polymer and hence differs from the pore heterogeneity \( \epsilon_p \). The variable \( c = c_+ \) denotes the density of \( \text{Li}^+ \)-ions. The mean field equations describing interstitial and electron transport inside a solid crystal read in the pore scale as follows
\[
\begin{align*}
\partial_t c_+^{\epsilon_p} &= \text{div} \left( M_+ \nabla \left( f'_p(c_+^{\epsilon_p}) - \lambda \Delta c_+^{\epsilon_p} \right) \right) \quad \text{in } D_s^{\epsilon_p}, \\
-\text{div}(\sigma_s \nabla \phi^{\epsilon_p}) &= 0 \quad \text{in } D_s^{\epsilon_p},
\end{align*}
\]
where the electric conductivity of the solid intercalation compound is $\sigma_s$. We note that the Poisson equations \([2.33]_3\) and \([2.24]_2\) can be written as a single equation for the electric potential $\phi^{ep}$ by

$$-\text{div}(\varepsilon(\mathbf{x}/\varepsilon_p)\nabla\psi^{ep}) = e(z_+c^{ep}_p + z_-c^{ep}_-\chi_{D^{ep}_s})$$

valid on the whole domain $D$ for the combined permeability and conductivity parameter

$$\varepsilon(\mathbf{x}/\varepsilon) := \varepsilon_p\chi_{Y_p}(\mathbf{x}/\varepsilon_p) + \sigma_s\chi_{Y_s}(\mathbf{x}/\varepsilon_p),$$

and with the characteristic function $\chi_{D^{ep}_s}(\mathbf{x}) = 1$ if $\mathbf{x} \in D^{ep}_s$. In \([2.26]\), we employ the microscopic variables and parameters respectively, we can identify the overpotential in \([2.28]\) by

$$\chi_{D^{ep}_s}(\mathbf{x}) = \frac{\chi_{D^{ep}_s}(\mathbf{x})}{\chi_{D^{ep}_s}(\mathbf{x})}$$

by passing from the solid phase and the polymer phase to the interface $I^{ep}$, respectively. The current $R^{ep} = R^{ep}(c^{ep}_p, c^{ep}_s, \eta^{ep}, U^{ep})$ is defined by the Butler-Volmer kinetics \([2.20]\) extended here towards the highly heterogeneous composite cathode setting indicated by the pore heterogeneity $\varepsilon_p$, that is,

$$R^{ep} = i_{ps} \left[ c^{ep}_s \exp \left( \frac{\alpha_a F}{RT} (\eta^{ep} - U^{ep}) \right) - \frac{(c^{ep}_s - c^{ep}_p)}{c^{ep}_s} \exp \left( -\frac{\alpha_{sm} F}{RT} (\eta^{ep} - U^{ep}) \right) \right],$$

where $i_{ps} = Fk_{\text{ref}}(c^{ep}_s - c_{\text{sm}})\alpha_{ep}(c^{ep}_s)\alpha_a$ plays the role of an exchange current density and $c^{ep}_s = \exp(\alpha_{sm})$ brings the term in the angled brackets into dimensionless form. For the limits $\lim_{x \rightarrow I^{ep}_p}$ and $\lim_{x \rightarrow I^{ep}_p}$, which denote passing from the solid phase and the polymer phase to the interface $I^{ep}$, respectively, we can identify the overpotential in \([2.28]\) by

$$\eta^{ep} = \lim_{x \rightarrow I^{ep}_p} \psi^{ep} - \lim_{x \rightarrow I^{ep}_p} \psi^{ep}.$$ 

Equation \([2.28]\) additionally depends on the maximum capacity of ions in the polymer phase $c^{ep}_{\text{sm}} = 3920\text{mol/m}^3$ as well as in the solid crystal $c^{ep}_s = 29000\text{mol/m}^3$. We also recall from equation \([2.20]\) that a fitting to experimental data \([14, 50]\) provides

$$U^{ep} = 2.17 + \frac{RT}{F} (-0.000558c^{ep}_p |^{I^{ep}_p} + 8.1).$$

Finally, we bring the equations \([2.22], [2.24], [2.25], \) and \([2.27]\) into dimensionless form by using the following variables and parameters

$$\tilde{u}^{\epsilon D} = \frac{u^{\epsilon D}}{U_{\text{ref}}}, \quad c^{\epsilon \pm} = \frac{c^{\epsilon \pm}}{c_{\text{ref}}}, \quad \tilde{\psi} = \frac{F\psi}{RT}, \quad \tilde{t} = \frac{t}{\tau},$$

$$\tilde{x} = \frac{x}{L}, \quad \eta = \frac{2c_{\text{ref}}RTL}{U_{\text{ref}}\mu}, \quad Pe = \frac{LU_{\text{ref}}}{D},$$

M. Schmuck

Homogenized composite cathode equations

11
where $\tau$ is either the diffusion time $\tau_D := \frac{L^2}{D}$, the interfacial transport time $\tau_s := \frac{L^2}{M_s}$, or the convection time $\tau_u = \frac{L}{U_{ref}}$. $U_{ref}$ is a reference velocity and $c_{ref}$ a reference salt concentration. We also use the identity $\frac{L_0^2}{\epsilon} = \frac{RT}{\psi}$ and the electric potential $\psi$ stands for the electric potentials of the solid phase $\psi_s$ and of the liquid phase $\psi_p$. The parameter $\lambda_D := \left(\frac{\epsilon_p k_B T}{2e^2 c_{ref}}\right)^{1/2}$ denotes the dimensionless Debye length and $\sigma := \frac{\sigma_{ref}}{\sigma_{ref}}$ the dimensionless electric conductivity. We set the reference conductivity to the bulk conductivity in the electrolyte phase, i.e., $\sigma_{ref} = \frac{\epsilon_p D}{\psi}$. For notational convenience, we assume $M = M_+ = M_-$, and hence $D = D_+ = D_-$, and we will subsequently drop the tilde from dimensionless variables. With Einstein’s relation we then have $D = k_B T M$. Moreover, we note that the convection-diffusion-electromigration equation reads with the above scalings as follows

$$\frac{L^2}{\tau D} \frac{\partial c^p_s}{\partial t} + P e \mathbf{u}^D \nabla c^p_s = \text{div} \left( z_p c^p_s \psi \right).$$

As noted earlier in this section, in the composite cathode one expects a small $Re = Pe/\Pr$ but a large Prandt number $Pr := \frac{\nu}{\rho}$, e.g., in solute transport in groundwater flow $D = 10^{-5} \text{cm}^2/\text{s}$, $\nu = 10^{-2} \text{cm}^2/\text{s}$, and hence $Pr = 10^3$, where $\nu$ is the the kinematic viscosity and $\rho$ the density. Therefore, we allow for $Pe = \mathcal{O}(1)$ \cite{31}.

Herewith and after choosing $\tau = \tau_u$, and setting $\frac{\tau}{\tau_u} = 1$ for simplicity, we obtain the following dimensionless microscopic formulation

\begin{equation}
\begin{aligned}
\text{(micro (SE))} & \quad \left\{ \begin{array}{ll}
-\epsilon^2 D \mathbf{u}^{se} + \nabla p^{se} = F^{se} := -\eta (z_+ c^p_+ - z_- c^p_-) \nabla \psi^{se} & \text{in } D^{se}, \\
\text{div } \mathbf{u}^{se} = 0 & \text{in } D^{se}.
\end{array} \right.
\end{aligned}
\tag{2.32}
\end{equation}

\begin{equation}
\begin{aligned}
\text{(micro (E1))} & \quad \left\{ \begin{array}{ll}
P e \left( \partial_t c^p_+ + u^p \cdot \nabla c^p_+ \right) = \text{div} \left( \nabla c^p_+ + z_+ c^p_+ \nabla \psi^{se} \right) & \text{in } D^{se}, \\
P e \left( \partial_t c^p_- + u^p \cdot \nabla c^p_- \right) = \text{div} \left( \nabla c^p_- - z_- c^p_- \nabla \psi^{se} \right) & \text{in } D^{se}.
\end{array} \right.
\end{aligned}
\tag{2.33}
\end{equation}

\begin{equation}
\begin{aligned}
\text{(micro (S))} & \quad \left\{ \begin{array}{ll}
\partial_t c^s_+ = \text{div} \left( \nabla \left( f^s_+ (c^p_s) - \lambda \Delta c^s_+ \right) \right) & \text{in } D^{se}, \\
\text{div } \mathbf{n}^{sp} = 0 & \text{in } D^{se}.
\end{array} \right.
\end{aligned}
\tag{2.34}
\end{equation}

\begin{equation}
\begin{aligned}
\text{(micro (P))} & \quad \left\{ \begin{array}{ll}
\text{div } \left( \nabla \left( f^s_+ (c^s_+) - \lambda \Delta c^s_+ \right) \right) & \text{in } D^{se}, \\
\text{div } \left( \sigma \nabla \psi^{sp} \right) = 0 & \text{in } D^{se}.
\end{array} \right.
\end{aligned}
\tag{2.35}
\end{equation}

\begin{equation}
\begin{aligned}
\text{(micro (I))} & \quad \left\{ \begin{array}{ll}
\epsilon_p \beta_+ R^p (c^p_+, c^s_+, \eta^p, U^p) = \left( \nabla c^p_+ + z_+ c^p_+ \nabla \psi^{se} \right) - \mathbf{u}^{se} c^p_+ \cdot \mathbf{n}_{ps} & \text{on } I^{se}, \\
0 = \left( \nabla c^p_- - z_- c^p_- \nabla \psi^{se} \right) - \mathbf{u}^{se} c^p_- \cdot \mathbf{n}_{ps} & \text{on } I^{se}, \\
\epsilon_p \beta_0 R^p (c^s_+, \eta^p, U^p) = -\nabla \left( f^s_+ (c^s_+) - \lambda \Delta c^s_+ \right) \cdot \mathbf{n}_{sp} & \text{on } I^{se}, \\
\epsilon_p \beta_0 R^p (c^s_+, c^s_+, \eta^p, U^p) = \sigma \nabla \psi^{sp} \cdot \mathbf{n}_{sp} & \text{on } I^{se}, \\
\frac{\sigma_{ref}}{\sigma_{ref}} \nabla \psi^{sp} \cdot \mathbf{n}_{sp} = \frac{\epsilon_p}{\epsilon_s} \psi^{se} \psi^{sp} \cdot \mathbf{n}_{sp} & \text{on } I^{se}, \\
\mathbf{u}^{se} = 0 & \text{on } I^{se}.
\end{array} \right.
\end{aligned}
\tag{2.36}
\end{equation}

where the parameters coupling the Butler-Volmer reactions to the different charge transport equations are defined by $\beta_+ = \frac{i_p L}{e D}$, $\beta_0 = \frac{i_p L}{e M}$, and $\beta_0 = \frac{F \sigma_{ref}}{RT \lambda_{ref}}$ for $\sigma_{ref} = \frac{\epsilon_p D}{\psi}$. A summary of physical and dimensionless parameters are given in Tab.\cite{2}.
3 Main results: Effective macroscopic equations

Our main result is the reliable and systematic derivation of a novel set of effective macroscopic composite cathode equations that take the crucial chemical and transport processes described in Section 2.2 into account: (a) ionic transport; (b) interfacial reactions; (c) intercalation dynamics under a possible phase transformation; (d) electron transport.

The subsequent upscaling result relies on the following property.

**Definition 3.1 (Local Thermodynamic Equilibrium (LTE))** The chemical potentials \( \mu_{\pm}(C^\pm, \Psi) = \log C^\pm \pm \Psi \) and \( \mu_s(C_s) = f'_r(C_s) - \frac{1}{q} \text{div} \left( \hat{M} \nabla C_s \right) \) are said to be in local thermodynamic equilibrium if for every \( k \in \mathbb{N}, 1 \leq k \leq d, \)
\[
\frac{\partial \mu_k(C^\pm, \Psi)}{\partial x_k} = \begin{cases} 
0 & \text{if it appears in the cell problem in } Y \times D, \\
\frac{\partial \mu_k(C^\pm, \Psi)}{\partial x_k} & \text{if it appears on the macroscale } D,
\end{cases}
\]
and similarly
\[
\frac{\partial \mu_s(C_s)}{\partial x_k} = \begin{cases} 
0 & \text{if it appears in the cell problem in } Y \times D, \\
\frac{\partial \mu_s(C_s)}{\partial x_k} & \text{if it appears on the macroscale } D,
\end{cases}
\]
for \( i = +, -, \) where \( C^\pm, \Psi, \) and \( C_s \) are the upscaled/slow variables solving (3.39) below and do not depend on the fast microscale \( Y. \)

With the help of the asymptotic two-scale expansion method, we derive the following

**Main result:** (Upscaled composite cathode equations) The microscopic composite cathode formulation based on the equations (2.32), (2.33), (2.34), and (2.36) admits under local thermodynamic equilibrium (Definition 3.1) the following upscaled/homogenized equations
\[
\begin{align*}
\mathbf{V}(x,t) &= -\frac{1}{\mu} (f^0 - \nabla P), & \text{in } D, \\
div \mathbf{V} &= 0, & \text{in } D, \\
p \partial_t C^+ + Pe \mathbf{V} \cdot \nabla C^+ &= \text{div} \left( \hat{M} \nabla C^+ + z_+ C^+ \hat{M} \nabla \Psi \right) - \bar{\beta}_+ R(C^+, C_s, \eta^0, U^0), & \text{in } D, \\
p \partial_t C^- + Pe \mathbf{V} \cdot \nabla C^- &= \text{div} \left( \hat{M} \nabla C^- - z_- C^- \hat{M} \nabla \Psi \right), & \text{in } D, \\
- \text{div} (\hat{v} \nabla \Psi) &= p (z_+ C^+ + z_- C^-), & \text{in } D, \\
- \text{div} (\hat{\Sigma} \nabla \Psi) &= \bar{\beta}_0 R(C^+, C_s, \eta^0, U^0), & \text{in } D, \\
q \partial_t C_s &= \text{div} \left( \hat{M}_s \left( \nabla f'_r(C_s) + \frac{1}{q} \text{div} \left( \hat{M}_s \nabla C_s \right) \right) \right) + \bar{\beta}_s R(C_s, C_s, \eta^0, U^0), & \text{in } D,
\end{align*}
\]

where \( p = \frac{\lambda_s}{|Y|}, q = 1 - p, f^0 = -\eta (C_+ - C_-) \hat{M} \nabla \Psi, \bar{\beta}_+ = \frac{\eta \lambda_s |L|}{cD}, \bar{\beta}_0 = \frac{F_s r T}{\eta \sigma_{\text{ref}}}, \bar{\beta}_s = \frac{\eta L s}{\eta M_s}, \eta^0 = \Psi_s - \Psi, U^0 = 2.17 + \frac{F_s r T}{k} (-0.000558 C_s{2.56} + 8.1), \) and the material’s correction tensors \( \hat{\kappa} = \{ \hat{\kappa}_{ij} \}_{i,j=1}^d, \)
\[
\hat{M} = \{ \hat{M}_{ij} \}_{i,j=1}^d, \quad \hat{M} = \{ \hat{M}_{ij} \}_{i,j=1}^d, \quad \hat{v} = \{ \hat{v}_{ij} \}_{i,j=1}^d, \quad \hat{\Sigma} = \{ \hat{\Sigma}_{ij} \}_{i,j=1}^d, \quad \text{and } \hat{M}_s = \{ \hat{M}_s^s \}_{i,j=1}^d \text{ are defined by}
\]
\[
\hat{\kappa}_{ij} = -\frac{1}{\mu |Y|} \int_{Y} \omega^i_j(y) dy, \quad \hat{v}_{ij} = \frac{1}{|Y|} \int_{Y} \lambda_D \left( \delta_{ik} - \delta_{ij} \frac{\partial \xi_k(y)}{\partial y_j} \right) dy, \quad \hat{M}_{ij} = \frac{1}{|Y|} \int_{Y} \delta_{ij}(y) \left( \delta_{ik} - \delta_{ij} \frac{\partial \xi_k(y)}{\partial y_j} \right) dy, \quad \hat{M}_s^s = \frac{1}{|Y|} \int_{Y} \delta_{ij}(y) \left( \delta_{ik} - \delta_{ij} \frac{\partial \xi_k(y)}{\partial y_j} \right) dy,
\]
\[
\hat{d}_{ik} = \frac{1}{|Y|} \int_{Y} d_{ij}(y) \left( \delta_{ik} - \delta_{ij} \frac{\partial \xi_k(y)}{\partial y_j} \right) dy, \quad \hat{\sigma}_{ik} = \frac{1}{|Y|} \int_{Y} \sigma \left( \delta_{ik} - \delta_{ij} \frac{\partial \xi_k(y)}{\partial y_j} \right) dy.
\]
The correctors \( w_i^j, \xi^k, \xi^k_0, \) and \( \xi^k \) solve the reference cell problems \( (3.48), (3.63)_2, (3.72) \), and \( (3.63)_1 \), respectively.

Before we derive these effective macroscopic formulation, we provide values for the parameters used in general Li batteries, see Tab. 2.

3.1 Derivation of the upscaled cathode equations \((3.39)\).

As the upscaling involves several equations, we will start with the Stokes equations driven by a Coulomb force \( f^{\psi}_D \). Then we consider the PNP system, and finally we look at the phase field equation describing the Li-intercalation process.

**Homogenizing the generalized Stokes equations \((2.32)_1\):**

Our derivation gives an extension of the classical formal homogenization result \[23\] towards Coulomb driving forces \[24, 40, 41, 42\].

**Step 1: (Asymptotic expansion)** We make the ansatz

\[
\begin{align*}
\mathbf{u}^{\psi D} (\mathbf{x}) &= \mathbf{U}(\mathbf{x}, \mathbf{y}_D) + \epsilon_D \mathbf{u}^1 (\mathbf{x}, \mathbf{y}_D) + \epsilon_D^2 \mathbf{u}^2 (\mathbf{x}, \mathbf{y}_D) + \cdots, \\
p^{\psi D} (\mathbf{x}) &= \mathbf{P}(\mathbf{x}, \mathbf{y}_D) + \epsilon_D \mathbf{p}^1 (\mathbf{x}, \mathbf{y}_D) + \epsilon_D^2 \mathbf{p}^2 (\mathbf{x}, \mathbf{y}_D) + \cdots.
\end{align*}
\]

\((3.41)\)

The microscale \( \mathbf{y}_D = \mathbf{x}/\epsilon_D \in Y_D \) is \( Y_D \)-periodic as in Section 2.2, where we introduced the microscopic formulation of the composite cathode based on a reference FePO\(_4\)-particle configuration \( Y \) and a reference flow/filtration cell \( Y_D \).
We insert (3.41) into (2.32). This leads to the following problem where we only state the leading order terms,

\[ -\varepsilon D^{-1}\nabla y p(x, y_D) + \varepsilon D^0 \left\{ \mu \Delta y_D U(x, y_D) - \left( \nabla y_D p^1(x, y_D) + \nabla x p(x, y_D) \right) \right\} \]
\[ + \varepsilon D \left( \ldots \right) + \text{h.o.t.} = f^p = -\varepsilon (\sum_{i} c_{i}^{p}) \nabla \phi_{p}^{i}, \quad \text{in } Y_{D}^{p}, \]

(3.42)

\[ \varepsilon D^{-1} \text{div}_{y_D} U(x, y_D) + \varepsilon D^0 \left( \text{div}_{y_D} u^1(x, y_D) + \text{div}_{x} U(x, y_D) \right) \]
\[ + \varepsilon D \left( \ldots \right) + \text{h.o.t.} = 0, \quad \text{in } Y_{D}^{p}, \]

(3.43)

\[ \varepsilon D^0 U(x, y_D) + \varepsilon D u^1(x, y_D) + \text{h.o.t.} = 0 \quad \text{on } I_0. \]

(3.44)

The variable $I_0 := \partial Y_{D}^{p} \cap \partial Y_{D}^{p}$ denotes the solid-pore interface on the level of the reference cell $Y_{D}$. Higher order terms are referred to by h.o.t..

**Step 2: (Comparing terms of equal order)** The lowest order problem in Step 1 is obtained by comparing coefficients of the terms of order $\varepsilon D^{-1}$, i.e., we obtain the equations

\[ \nabla y_D p(x, y_D) = 0, \quad \text{in } Y_{D}^{p}, \]
\[ \text{div}_{y_D} U(x, y_D) = 0, \quad \text{in } Y_{D}^{p}. \]

(3.45)

This allows us to conclude that the leading order pressure component $p$ is independent of the microscale $y_D$ but not for leading order fluid velocity $U$.

At the next order $O(\varepsilon D^0)$, we obtain

\[ -\mu \Delta y_D U(x, y_D) + \left( \nabla y_D p^1(x, y_D) + \nabla x p(x, y_D) \right) = f^p = -\varepsilon (\sum_{i} c_{i}^{p}) \nabla \phi_{p}^{i}, \quad \text{in } Y_{D}^{p}, \]
\[ \text{div}_{y_D} u^1(x, y_D) + \text{div}_{x} U(x, y_D) = 0, \quad \text{in } Y_{D}^{p}. \]

(3.46)

**Step 3: (Ansatz for first order terms)** This step is not entirely standard and requires physical intuition. Making the usual ansatz for the pressure $p^1$ in the asymptotic expansion and treating the fluid velocity $U$ instead of $u^1$ in the same way, which is motivated by its dependence on the microscale $y_D$, i.e.,

\[ p^1(x, y_D) = \sum_{j=1}^{d} \left( f_{j}^{p} - \frac{\partial P(x)}{\partial x_j} \right) \pi_{j}(y_D), \]

\[ U(x, y_D) = \frac{1}{\mu} \sum_{j=1}^{d} \left( f_{j}^{p} - \frac{\partial P(x)}{\partial x_j} \right) w_{j}(y_D), \]

(3.47)

then problem (3.46) turns into the following

\[ \text{(Cell Problem)} \left\{ \begin{array}{l}
\Delta y_D w_{j}(y_D) + \nabla y_D \pi_{j}(y_D) = e_{j}, \quad \text{in } Y_{D}^{p}, \\
\text{div}_{y_D} w_{j}(y_D) = 0, \quad \text{in } Y_{D}^{p}, \\
w_{j}(y_D) = 0, \quad \text{on } I_0,
\end{array} \right. \]

(3.48)
via ansatz (3.47) as well as into Darcy’s law after integrating (3.47) over the pore space $Y_D^p$, i.e.,

$$
V(x,t) = \frac{|Y_D^p|}{|Y_D|} M_{Y_D^p}(U(x,y_D)) = -\frac{1}{\mu} \hat{\kappa}(f^{\varepsilon} - \nabla_x P(x)), \tag{3.49}
$$

where the hydraulic conductivity/permeability tensor $\hat{\kappa} := \{\kappa_{ij}\}_{i,j=1}^d$ is defined by the volume average

$$
\kappa_{ij} = -\frac{1}{\mu |Y_D|} \int_{Y_D^p} w^2_{ij}(y_D)dy_D. \tag{3.50}
$$

It leaves to show that the effective Darcy velocity $V$ is divergence free, that means, that it satisfies (2.32). To this end, we can make use of equation (3.46), which leads after integration over the pore space $Y_D^p$ and with the help of Gauss’ theorem to

$$
\text{div}_x V(x) = \int_{\partial Y_D} n \cdot u^1(x,y_D)do(y_D) - \int_{I_0} n \cdot u^1(x,y_D)do(y_D) = 0, \tag{3.51}
$$

where we used the $Y_D$-periodicity and the homogeneous boundary condition (3.44) at order $O(\varepsilon_D)$.

Finally, we note that once we have the upscaling result for the transport equations (2.33), which are formulated with respect to the pore scale $l_p$, then we can also determine the upscaled form of the Coulomb force term $f^{\varepsilon}$ by $f^0$, i.e., by formally passing $\varepsilon \rightarrow 0$.

**Homogenizing the PNP system:**

The following derivation relies on homogenization results for the PNP system obtained in the context of microfluidics and soil mechanics such as [42, 43, 45]. The subsequent statements extend the derivation in [43] to include fluid flow.

**Step 1: (Asymptotic expansion)** We consider the asymptotic two-scale expansions

$$
c^{+}_{\varepsilon_p}(t,x,y) = C^+(t,x,y) + \varepsilon_p c^{+}(t,x,y) + \varepsilon^2_{p} c^{+}_2(t,x,y) + \text{h.o.t.},
$$

$$
\psi^{+}_{\varepsilon_p}(t,x) = \Psi(t,x,y) + \varepsilon_p \psi_1(t,x,y) + \varepsilon^2_{p} \psi_2(t,x,y) + \text{h.o.t.}. \tag{3.52}
$$

For notational convenience, we introduce for smooth enough functions $v_{\varepsilon_p}$ the following operators,

$$
A_s v_{\varepsilon_p}(x) := -\sum_{i,j=1}^N \frac{\partial}{\partial x_i} \left( \varepsilon(x/\varepsilon_p) \delta_{ij} \frac{\partial v_{\varepsilon_p}}{\partial x_j} \right),
$$

$$
= \left[ (\varepsilon_p^{-2} A_0 + \varepsilon_p^{-1} A_1 + A_2) v_{\varepsilon_p} \right](x,x/\varepsilon_p),
$$

$$
B_{s}^{\pm} v_{\varepsilon_p}(x) := -\sum_{i,j=1}^N \frac{\partial}{\partial x_i} \left( \delta_{ij} \frac{\partial v_{\varepsilon_p}}{\partial x_j} \right)
$$

$$
= \left[ (\varepsilon_p^{-2} B_0^{\pm} + \varepsilon_p^{-1} B_1^{\pm} + B_2^{\pm}) v_{\varepsilon_p} \right](x,x/\varepsilon_p), \tag{3.53}
$$

$$
B_{s}^{3} v_{\varepsilon_p}(x) := -\sum_{i,j=1}^N \frac{\partial}{\partial x_i} \left( v_{\varepsilon_p} \delta_{ij} \frac{\partial v_{\varepsilon_p}}{\partial x_j} \right)
$$

$$
= \left[ (\varepsilon_p^{-2} B_0^{3} + \varepsilon_p^{-1} B_1^{3} + B_2^{3}) v_{\varepsilon_p} \right](x,x/\varepsilon_p),
$$
where $A_i$ are related to the Poisson equation and are defined by,

$$
A_0 := -\sum_{i,j=1}^d \frac{\partial}{\partial y_i} \left( \varepsilon(y) \delta_{ij} \frac{\partial}{\partial y_j} \right),
$$

$$
A_1 := -\sum_{i,j=1}^d \frac{\partial}{\partial x_i} \left( \varepsilon(y) \delta_{ij} \frac{\partial}{\partial y_j} \right) - \sum_{i,j=1}^d \frac{\partial}{\partial y_i} \left( \varepsilon(y) \delta_{ij} \frac{\partial}{\partial x_j} \right),
$$

$$
A_2 := -\sum_{i,j=1}^d \frac{\partial}{\partial x_i} \left( \varepsilon(y) \delta_{ij} \frac{\partial}{\partial x_j} \right),
$$

(3.54)

The operators $B_i^\pm$ and $B_i^3$ related to the Nernst-Planck equations are defined for $c_\pm$ by,

$$
B_0^\pm := -\sum_{i,j=1}^d \frac{\partial}{\partial y_i} \left( \delta_{ij} \frac{\partial}{\partial y_j} \right),
$$

$$
B_1^\pm := -\sum_{i,j=1}^d \frac{\partial}{\partial x_i} \left( \delta_{ij} \frac{\partial}{\partial y_j} \right) - \sum_{i,j=1}^d \frac{\partial}{\partial y_i} \left( \delta_{ij} \frac{\partial}{\partial x_j} \right),
$$

$$
B_2^\pm := -\sum_{i,j=1}^d \frac{\partial}{\partial x_i} \left( \delta_{ij} \frac{\partial}{\partial x_j} \right),
$$

$$
B_0^3 := -z_\pm \sum_{i,j=1}^d \frac{\partial}{\partial y_i} \left( \delta_{ij} \frac{\partial}{\partial y_j} \right),
$$

$$
B_1^3 := -z_\pm \sum_{i,j=1}^d \frac{\partial}{\partial x_i} \left( \delta_{ij} \frac{\partial}{\partial y_j} \right) - z_\pm \sum_{i,j=1}^d \frac{\partial}{\partial y_i} \left( \delta_{ij} \frac{\partial}{\partial x_j} \right) - z_\pm \sum_{i,j=1}^d \frac{\partial}{\partial y_i} \left( \delta_{ij} \frac{\partial}{\partial y_j} \right),
$$

$$
B_2^3 := -z_\pm \sum_{i,j=1}^d \frac{\partial}{\partial x_i} \left( \delta_{ij} \frac{\partial}{\partial x_j} \right) - z_\pm \sum_{i,j=1}^d \frac{\partial}{\partial x_i} \left( \delta_{ij} \frac{\partial}{\partial y_j} \right) - z_\pm \sum_{i,j=1}^d \frac{\partial}{\partial y_i} \left( \delta_{ij} \frac{\partial}{\partial y_j} \right).
$$

(3.55)

The definitions (3.53), (3.54), and (3.55) allow to immediately obtain the following sequence of problems by equating terms of equal power in $\varepsilon_p$, i.e.,

$$
O(\varepsilon_p^{-2}): \begin{cases}
B_0^\pm C^\pm + B_0^3 C^\pm = 0 & \text{in } Y_p, \\
C^\pm \text{ is } Y_p\text{-periodic}.
\end{cases}
$$

$$
A_0 \Psi = 0 \quad \text{in } Y,
$$

(3.56)

$$
O(\varepsilon_p^{-1}): \begin{cases}
(B_0^\pm + B_0^3) c^\pm_1 + P \text{div}_y (u^\varepsilon p C^\pm) = - (B_1^\pm + B_1^3) C^\pm & \text{in } Y_p, \\
c^\pm_1 \text{ is } Y_p\text{-periodic}.
\end{cases}
$$

$$
A_0 \psi_1 = -A_1 \Psi \quad \text{in } Y,
$$

(3.57)

$$
\psi_1 \text{ is } Y\text{-periodic},
$$
The following ansatz,
\[ y \pe \]
where the convective terms can conclude that \( \Psi(t, x) \) is independent of the microscale \( y \in Y \). Entering with this result into further implies that also \( C^\pm(t, x) \) and \( \Psi(t, x) \) are independent of the microscale \( y \in Y_p \).

The next problem in the sequence, i.e., (3.57), has the following explicit form,
\[
\begin{aligned}
-\Delta_y C^+ - \text{div}_y (C^+ \nabla_y \Psi) &= 0 \quad \text{in } Y_p, \\
-\Delta_y C^- - \text{div}_y (C^- \nabla_y \Psi) &= 0 \quad \text{in } Y_p, \\
-\text{div}_y (\varepsilon(y) \nabla_y \Psi) &= 0 \quad \text{in } Y.
\end{aligned}
\]
Equation (3.59) is classical in elliptic homogenization theory [6, 10, 12, 23]. Hence, we immediately can conclude that \( \Psi(t, x) \) is independent of the microscale \( y \in Y \). Entering with this result into further implies that also \( C^\pm(t, x) \) and \( \Psi(t, x) \) are independent of the microscale \( y \in Y_p \).

The next problem in the sequence, i.e., (3.57), has the following explicit form,
\[
\begin{aligned}
-\Delta_y c^+_1 - \text{div}_y (z^\pm C^\pm \nabla_y \psi_1) + \text{Pediv}_y (u^{\epsilon D} C^\pm) &= \text{div}_y (z^\pm c^+_1 \nabla_y \Psi) + \text{div}_x \nabla_y C^+ \\
&\quad + \text{div}_x \nabla_x C^+ + \text{div}_y (z^\pm C^\pm \nabla_x \Psi) \quad \text{in } Y_p, \\
-\text{div}_y (\varepsilon(y) \nabla_y \psi_1) &= \text{div}_x (\varepsilon(y) \nabla_y \Psi) + \text{div}_y (\varepsilon(y) \nabla_x \Psi) \quad \text{in } Y,
\end{aligned}
\]
where the convective terms \( \text{Pediv}_y (u^{\epsilon D} C^\pm) \) disappear since \( C^\pm \) and \( u^{\epsilon D} \) are both independent of \( y \). The independence of \( C^\pm \) and \( \Psi \) from \( y \) together with the linearity of (3.60) motivates to make the following ansatz,
\[
c^+_1(t, x, y) = -\sum_{j=1}^d \xi^+_j(y) \frac{\partial C^\pm(t, x)}{\partial x_j}, \quad \text{and} \quad \psi_1(t, x, y) = -\sum_{j=1}^d \xi^{\psi}_j(y) \frac{\partial \Psi(t, x)}{\partial x_j}.
\]
With the local thermodynamic equilibrium property, i.e.,
\[
0 = \frac{\partial}{\partial x_j} \log C^\pm + z^\pm \frac{\partial}{\partial x_j} \Psi,
\]
we can simplify (3.60) to,
\[
\begin{aligned}
-\sum_{i,j=1}^N \frac{\partial}{\partial y_i} \left( \delta_{ij} \frac{\partial}{\partial y_j} \left( \xi^+_j(y) - y_j \right) \right) &= -\sum_{i,j=1}^N \frac{\partial}{\partial y_i} \left( \delta_{ij} \frac{\partial}{\partial y_j} \left( \xi^{\psi}_j(y) - y_j \right) \right) \quad \text{in } Y_p, \\
\xi^+_j(y) &= Y_p\text{-periodic and } M_{Y_p}(\xi^+_j) = 0, \\
\xi^{\psi}_j(y) &= Y\text{-periodic and } M_Y(\xi^{\psi}_j) = 0.
\end{aligned}
\]
System (3.63) defines the reference cell problems for the upscaled Poisson-Nernst-Planck equations describing binary symmetric electrolytes in porous media. Thanks to the simplification of (3.60) via (3.62), the well-posedness of (3.63) follows by Lax-Milgram’s theorem.
The last problem (3.58) is again well-posed by Lax-Milgram’s theorem or the Fredholm alternative. A necessary and sufficient condition for the existence and uniqueness of solutions to (3.63)
is the requirement that corresponding right-hand sides are zero after integrating over $Y_p$. Hence, we immediately obtain,

$$\left\{ \begin{array}{l} |Y_p| \partial_t C^+ + P e |Y_p| \text{div}_x (u^{\rho \phi} C^+) - \sum_{i,j,k=1}^d \left( \frac{\partial}{\partial x_i} \left( \delta_{ik} - \delta_{ij} \frac{\partial C^+}{\partial x_j} \right) \frac{\partial C^+}{\partial x_k} \right) \right) Y_p \\
- \sum_{i,j,k=1}^d \left( \frac{\partial}{\partial x_i} \left( 2C^+ \left\{ \delta_{ik} - \delta_{ij} \frac{\partial C^+}{\partial y_j} \right\} \frac{\partial \psi}{\partial x_k} \right) + 1 \right) Y_p = 0, \\
- \sum_{i,j,k=1}^d \left( \frac{\partial}{\partial x_i} \left( \varepsilon (y) \left\{ \delta_{ik} - \delta_{ij} \frac{\partial \psi}{\partial y_j} \right\} \frac{\partial \psi}{\partial x_k} \right) + 1 \right) Y_p = |Y_p| (C^+ - C^-). \end{array} \right.$$  
(3.64)

We note that $u^{\rho \phi}$ is not upscaled/homogenized here since this allows us to account for multiple scales such as the pore scale $l_p$, the Darcy scale $l_D$, and the macroscale $L$. For details regarding the verification of the cell problems with Lax-Milgram’s theorem or the Fredholm alternative [12], we refer the interested reader also to [14] where these tools are applied in a related problem by a modified asymptotic expansion.

It leaves to homogenize the right-hand side of the Stokes equations (2.32), which is scaled with respect to the pore scale $l_p$. With the corrector $\xi^k\psi$ we immediately obtain at the level $O(\epsilon^0)$ that the effective Coulomb force term is $f^0 = -\eta (C_+ - C_-) M \nabla \Psi_p$ since at $O(\epsilon^0_p)$ we have with (3.61)

$$-\eta (C_+ - C_-) (\nabla_x \Psi_p + \nabla_y \psi) = -\eta (C_+ - C_-) \left( \sum_{i,j,k=1}^d \left( \delta_{ik} - \delta_{ij} \frac{\partial \Psi_p}{\partial y_j} \right) \frac{\partial \psi}{\partial x_k} \right).$$

\[ \square \]

**Homogenizing the phase field intercalation equation**

**Step 1: (Asymptotic expansion)** The derivation of the phase field equations follows the essential steps presented in [17] and which we repeat here for the reader’s convenience. The heterogeneity parameter $\epsilon = \epsilon_p$ is the pore scale as for the ionic transport in the polymer solution.

In the context of asymptotic two-scale expansions, the Laplace operator $\Delta$ can be written as follows,

$$\mathcal{A}_0 = -\sum_{i,j=1}^d \frac{\partial}{\partial y_i} \left( \delta_{ij} \frac{\partial}{\partial y_j} \right), \quad \mathcal{A}_1 = -\sum_{i,j=1}^d \left[ \frac{\partial}{\partial x_i} \left( \delta_{ij} \frac{\partial}{\partial y_j} \right) + \frac{\partial}{\partial y_i} \left( \delta_{ij} \frac{\partial}{\partial x_j} \right) \right], \quad \mathcal{A}_2 = -\sum_{i,j=1}^d \frac{\partial}{\partial x_j} \left( \delta_{ij} \frac{\partial}{\partial x_j} \right),$$

(3.65)

such that we can identify $\mathcal{A}_\epsilon := \epsilon^{-2} \mathcal{A}_0 + \epsilon^{-1} \mathcal{A}_1 + \mathcal{A}_2 = \Delta$. We account for the multiscale nature of strongly heterogeneous environments [13] [23] [31] by the following ansatz

$$\eta^\epsilon \approx \eta_0 (x, y, t) + \epsilon \eta_1 (x, y, t) + \epsilon^2 \eta_2 (x, y, t) + \ldots, \quad \text{for} \quad \eta \in \{ w, \phi \}.$$  
(3.66)

Before we can insert (3.66) into the microscopic formulation (2.34), we approximate the derivative of the nonlinear homogeneous free energy density $f_r$ by a Taylor expansion around the homogenized order parameter $\phi_0$, that means,

$$f_r (\phi^\epsilon) \approx f_r (\phi_0) + f_r' (\phi_0) (\phi^\epsilon - \phi_0) + \frac{1}{2} f_r'' (\phi_0) (\phi^\epsilon - \phi_0)^2 + O \left( (\phi^\epsilon - \phi_0)^3 \right).$$  
(3.67)
where $\phi_0$ denotes the leading-order term in (3.66). Substituting (3.66) and (3.67) into (2.34), which we split into two second order problems as suggested in [46], and using (3.65) provides the following sequence of problems

$$
\mathcal{O}(\varepsilon^{-2}): \begin{cases} \\
\mathcal{A}_0 [\lambda w_0 + f_r(\phi_0)] = 0 \\
\text{under no flux b.c. and with } w_0 \text{ is } Y_s\text{-periodic,} \\
\mathcal{A}_0 \phi_0 = 0 \\
\text{with } n_{sp} \cdot \nabla \phi_0 = 0 \text{ on } \partial Y_s := \partial Y_s \cap Y_p \text{ and } \phi_0 \ Y_s\text{-periodic}, \\
\end{cases} \quad \text{in } Y_s, \tag{3.68}
$$

$$
\mathcal{O}(\varepsilon^{-1}): \begin{cases} \\
\mathcal{A}_0 [\lambda w_1 + f_r'(\phi_0) \phi_1] = -\mathcal{A}_1 [\lambda w_0 + f_r(\phi_0)] \\
\text{under no flux b.c. and } w_1 \ Y_s\text{-periodic,} \\
\mathcal{A}_0 \phi_1 = -\mathcal{A}_1 \phi_0 \\
\text{with } n_{sp} \cdot \nabla \phi_1 = 0 \text{ on } \partial Y_s \cap \partial Y_p \text{ and } \phi_1 \ Y_s\text{-periodic,} \\
\end{cases} \quad \text{in } Y_s, \tag{3.69}
$$

$$
\mathcal{O}(\varepsilon^0): \begin{cases} \\
\mathcal{A}_0 \left[ \lambda w_2 + \left( \frac{1}{2} f''_r(\phi_0) \phi_2^2 + f'_r(\phi_0) \phi_2 \right) \right] \\
= -\mathcal{A}_2 \left[ \lambda w_0 + f_r(\phi_0) + \mathcal{A}_1 [\lambda w_1 - f_r'(\phi_0) \phi_1] \right] \\
\quad - \partial_s \mathcal{A}_2^{-1} w_0 \\
\text{under no flux b.c. and with } w_2 \ Y_s\text{-periodic,} \\
\mathcal{A}_0 \phi_2 = -\mathcal{A}_2 \phi_0 - \mathcal{A}_1 \phi_1 + w_0 \\
\text{with } n_{sp} \cdot \nabla \phi_2 = g_\varepsilon \text{ on } \partial Y_s \cap \partial Y_p \text{ and } \phi_2 \ Y_s\text{-periodic,} \\
\end{cases} \quad \text{in } Y_s, \tag{3.70}
$$

**Step 2: (Analysis of the sequence of problems)** The first problem (3.68) immediately implies that the leading-orders $\phi_0$ and $w_0$ are independent of the microscale $y$ [43, 31]. This suggests the following ansatz for $w_1$ and $\phi_1$, i.e.,

$$
w_1(x, y, t) = - \sum_{k=1}^d \xi_w^k(y) \frac{\partial w_0}{\partial x_k}(x, t), \quad \phi_1(x, y, t) = - \sum_{k=1}^d \xi_\phi^k(y) \frac{\partial \phi_0}{\partial x_k}(x, t) = \phi_1(x, y, t). \tag{3.71}
$$

Inserting (3.71) into (3.69) provides an equation for the correctors $\xi_w^k$ and $\xi_\phi^k$. The resulting equation for $\xi_w^k$ can be immediately written for $1 \leq k \leq d$ as,

$$
\xi_w^k: \begin{cases} \\
\xi_w^k \cdot \left( \sum_{i,j=1}^d \delta_{ij} \frac{\partial}{\partial y_i} \left( \delta_{ij} - \partial_{ij} \frac{\partial \xi_w^k}{\partial y_j} \right) \right) = -\text{div} \left( e_k - \nabla_y \xi_w^k \right) = 0 \quad \text{in } Y_s, \tag{3.72}
\end{cases}
$$

for $\xi_w^k(y)$ $Y$-periodic with $\mathcal{M}_Y(\xi_w^k) = 0$ and associated boundary condition $n \cdot \left( \nabla_y \xi_w^k + e_k \right) = 0$ on $\partial Y_s^w := \partial Y_s \cap \partial Y_p$.

To study (3.69)$_1$, we first rewrite $\mathcal{B}_0 [f'_r(\phi_0) \phi_1]$ and $\mathcal{B}_1 f_r(\phi_0)$ as follows

$$
\mathcal{A}_0 [f'_r(\phi_0) \phi_1] = - \sum_{k,i,j=1}^d \frac{\partial}{\partial y_i} \left( \delta_{ij} \frac{\partial \xi_\phi^k}{\partial y_j} \frac{\partial f_r(\phi_0)}{\partial x_k} \right), \quad \mathcal{A}_1 f_r(\phi_0) = \sum_{i,j=1}^d \frac{\partial}{\partial y_i} \left( \delta_{ij} \frac{\partial f_r(\phi_0)}{\partial x_j} \right). \tag{3.73}
$$

Doing the same for $w_1$ and $w_0$ and using (3.71) leads then to

$$
- \lambda \sum_{k,i,j=1}^d \frac{\partial}{\partial y_i} \left( \delta_{ij} \frac{\partial w_1}{\partial x_j} - \frac{\partial \xi_w^k}{\partial y_j} \frac{\partial w_0}{\partial x_k} \right) = \sum_{k,i,j=1}^d \frac{\partial}{\partial y_i} \left( \delta_{ij} \left( \frac{\partial x_k}{\partial x_j} - \frac{\partial \xi_w^k}{\partial y_j} \frac{\partial x_k}{\partial x_j} \right) \right). \tag{3.74}
$$
in $Y_s$. Since the chemical potential $\mu(\phi) - \frac{\delta E(\phi)}{\delta \phi}$ is locally in thermodynamic equilibrium, we finally obtain the reference cell problem for $\xi^k_\phi$, $1 \leq k \leq d$, for given $\xi^k_\phi$

\[
\left\{ - \sum_{i,j=1}^d \frac{\partial}{\partial y_j} \left( \delta_{ik} - \delta_{ij} \frac{\partial \xi^k_\phi}{\partial y_j} \right) = - \sum_{i,j=1}^d \frac{\partial}{\partial y_i} \left( \delta_{ik} - \delta_{ij} \frac{\partial \xi^k_\phi}{\partial y_i} \right) \right\} \text{ in } Y_s, \tag{3.75}
\]
where $\xi^k_\phi(y)$ is $Y$-periodic with boundary condition $\sum_{i,j=1}^d \int_{Y_s} \left( \delta_{ij} \frac{\partial \xi^k_\phi}{\partial y_j} \right) \, dy = 0$ on $\partial Y^w_s = \partial Y_s \cap \partial Y_p$ and $\mathcal{M}_{Y_s}(\xi^k_\phi) = 0$.

**Step 3: (Second order problem: upscaled equation)** The last problem (3.70) then gives the upscaled equations by a solvability constraint, i.e., the Fredholm alternative. Hence, the solvability of (3.70) is achieved by setting

\[
- \sum_{i,k=1}^d \sum_{j=1}^d \int_{Y_s} \left( \delta_{ik} - \delta_{ij} \frac{\partial \xi^k_\phi}{\partial y_j} \right) \, dy \right] \frac{\partial^2 \phi_0}{\partial x_i \partial x_k} = |Y_s| w_0 + \tilde{g}_0. \tag{3.76}
\]
where \(\tilde{g}_0 := -\frac{\gamma}{\epsilon_h} \int_{\partial Y^w_s} \left( a_1 \chi_{\partial y} \phi_0 + a_2 \chi_{\partial y} \phi_0 \right) \, do(y)\) and $\partial Y^w_s = \partial Y^w_1 \cup \partial Y^w_2$.

(3.76) can be written compactly as 

\[
- \Delta_{\tilde{M}_s} \phi_0 := - \text{div} \left( \tilde{M}_s \nabla \phi_0 \right) = qw_0 + \tilde{g}_0 \quad \text{by } (3.40). \tag{3.40}_1
\]
Applying the same ideas to equation (3.70) leads to

\[
\int_{Y_s} \left\{ - \lambda (\mathcal{A}_2 w_0 + \mathcal{A}_1 w_1) - \frac{1}{\lambda} \mathcal{A}_1 \left[ f'(\phi_0) \phi_1 \right] - \frac{1}{\lambda} \mathcal{A}_2 f_r(\phi_0) - \partial_r \mathcal{A}_2^{-1} w_0 \right\} \, dy = 0, \tag{3.77}
\]
where the first two terms can be rewritten with (3.75) by $\int_{Y_s} (\mathcal{A}_2 w_0 + \mathcal{A}_1 w_1) \, dy = \text{div} \left( \tilde{M}_s \nabla w_0 \right)$.

The third integrand in (3.77) becomes $- \mathcal{A}_1 \left[ f'(\phi_0) \phi_1 \right] = - \sum_{i,j=1}^d \delta_{ij} \sum_{k=1}^d \frac{\partial \xi^k_\phi}{\partial y_j} \frac{\partial^2 f_r(\phi_0)}{\partial x_k \partial x_j}$, where we applied the chain rule $\frac{\partial^2 f_r(\phi_0)}{\partial x_k \partial x_j} = f''_r(\phi_0) \frac{\partial \phi_0}{\partial x_k} \frac{\partial \phi_0}{\partial x_j} + f'_r(\phi_0) \frac{\partial^2 \phi_0}{\partial x_k \partial x_j}$ and integration by parts. Adding now the term $- \mathcal{A}_2 f(\phi_0)$ and using (3.72) finally gives $- \mathcal{A}_1 \left[ f'(\phi_0) \phi_1 \right] - \mathcal{A}_2 f_r(\phi_0) = \text{div} \left( \tilde{M}_s \nabla f_r(\phi_0) \right)$.

These considerations finally lead to the following effective equation for $\phi_0$, i.e.,

\[
d \frac{\partial \phi_0}{\partial t} = \text{div} \left( \tilde{M}_s \nabla f_r(\phi_0) \right) + \frac{1}{\nu} \text{div} \left( \tilde{M}_s \nabla \phi_0 \right) - \frac{1}{\lambda} \tilde{g}_0 \right). \tag{3.78}
\]

In the case where the homogeneous free energy $F_\nu$ is the classical double-well potential $F_r(\phi) = 1/4(\phi^2 - 1)^2$, one can verify the solvability of (3.78) along with the arguments in [33].

## 4 Discussion and conclusions

We have given a short account of widely used charge transport formulations in Li-ion battery systems. Based on well-accepted microscopic composite cathode equations which take into account ionic transport in the polymer electrolyte, electron transport as well as Li-intercalation undergoing a possible phase transformation in the solid phase, and Butler-Volmer reactions across the solid-electrolyte interface, we derived a novel upscaled/homogenized formulation. To the best of our knowledge, this seems to be the first two-scale asymptotic homogenization of composite cathodes.
for Li-batteries that also accounts for thermodynamically relevant phase transformations of crystalline host materials such as FePO$_4$. For a literature overview on recent results available, we refer the interested reader to Tab. 1.

The promising feature of being able to account for three different scales, i.e., pore scale $l_p$, Darcy’s scale $l_D$, and macroscale $L$, with the two-scale asymptotic expansion method by exploiting coupling of different physical processes, provides novel modelling opportunities not only in the context of batteries, but also in fuel cell systems, transport in porous media, and oil recovery for instance. We expect that the derived equations serve as a convenient computational model that allows to apply well-known numerical strategies available for homogeneous domains without ending up with high-dimensional discrete equations. Since the homogenization method is, compared to volume averaging, still less popular in applied sciences and engineering, we believe that the presented upscaling ideas and mathematical tools will become increasingly interesting in applications due to its reliable and systematic basis relying on rigorous convergence methods such as two-scale convergence [1, 32] or Gamma convergence, e.g. [13].
