ABSTRACT

Adsorption of Cu(II) ions onto a non-conventional plant biosorbents, mango leaf powder (MLP) developed from mature leaves of mango (Mangifera indica), was investigated in batch adsorption experiments. Process parameters which include initial metal ion concentration, adsorbent dosages, initial pH and temperature of solution were varied in order to evaluate their influence on the adsorption process. The results obtained indicate that the adsorption of Cu(II) on MLP is better at higher metal ion concentrations and lower adsorbent dosages. The maximum adsorption capacity was found to be 206.85 mg/g, which was obtained at 100 mg/L Cu(II) ion concentration and 0.4 g/L of MLP dosage. pH 4.5 was chosen as the optimum pH and better adsorption occurred at higher solution temperatures. Besides that, the adsorption of Cu(II) on MLP was found to fit the Freundlich isotherm.

Key Words: Biosorption, Mango leaf powder, Cu (II) ions, Heavy metals, Wastewater

INTRODUCTION

In moving towards the new era of science and technology, the world has seen major transformations in numerous aspects of life. At the heart of this tremendous advancement lies the rapid industrialization occurring at various parts of the globe. Despite being the source of many distinguished benefits for mankind, this revolution has also caused significant degradation to the environment, leading to detrimental effects to human and animal life. One widespread phenomenon which has drawn much attention is the contamination of toxic metals such as copper, lead, zinc, nickel and chromium in the aquatic environment, which are sourced from chemical industries such as petrochemicals, refineries, fertilizers, pulp and paper1. Heavy metal contamination may cause serious health problems such as cancer and brain damage, due to the accumulation in living tissues and organs2. Generally, metals could be divided into four distinguished categories which are toxic metals, strategic metals, precious metals and radionuclides. Among these, toxic metals
are the ones associated for causing serious environmental threats, making its removal from the aquatic environment essential. From the various types of toxic metals present in wastewater, copper was chosen for this biosorption studies with regard to its wide use in industry and potential pollution impact. Copper is listed as one of the pollutants found in wastewater by the United States Environmental Protection Agency (USEPA) in 1978\(^2\). In industrial waste, copper mainly appears to be in the form of the bivalent Cu(II), which is according to Ullmann’s encyclopaedia, more toxic than the metal itself. This is because it is soluble in water in its ionic form and can easily absorb into living organisms. High doses of copper in the aquatic environment generate toxicological concerns as it can deposit into the brain, liver, pancreas and myocardium\(^3\). Thus, Cu (II) concentrations of wastewater should be reduced to a value of at least 1.0 to 1.5 mg/L.

The increase of metal bearing effluents into the aquatic environment has caused progressive developments in wastewater treatment. A typical wastewater treatment plant is divided into several areas and the removal of metallic pollutants is performed mainly in the tertiary stage. Current developed methods in this stage include filtration, ion exchange, membrane separation, nutrient stripping and adsorption\(^4\). However, these methods have some limitations due to technical and economical constraints. The ion exchange process needs a high operational cost because it involves the use of excessive amounts of reagent for its resin regeneration. It also requires a high capital cost for the equipment used. Meanwhile, the membrane process application is limited by the condition of the membrane used. This membrane tends to be unstable in salty or acidic conditions and fouls by organic or inorganic substance present in the wastewater. The major disadvantage for the precipitation process is that it generates a toxic sludge that requires careful disposal as per regulations. For electrolysis, its inefficiency at low concentrations which causes incomplete metal ion recovery is one of its disadvantages\(^5\). Due to these factors, research has been conducted to study the use of natural adsorbents as an alternative, based on the economical and environmental point of view. The most current technique employed for metal removal from wastewater is biological adsorption or biosorption.

According to Mack et al. (2007), “biosorption” is the term given to the passive sorption and/or complexation of metal ions by biomass\(^6\). It is a reversible process where concentration of metal ions in solution decrease due to adsorption onto the solid phase until a dynamic equilibrium between the aqueous and solid phase is established. This technology which utilises natural biomass materials is very effective for the detoxification of metal-bearing industrial effluents. The biosorption process involves several mechanisms that differ qualitatively and quantitatively, depending on the origin of the biomass, the species used and its processing\(^7\). These mechanisms are generally based on physico-chemical interactions between metal ions and functional groups present on the cell surface, which include ion exchange, complexation, electrostatic attraction and microprecipitation\(^8\).
Various types of biomass have been used as the biosorbent for the removal of toxic metals. Among these, plant leaves are chosen in this study as they are proposed to be natural, simple and cheap biosorbents for the efficient removal of several heavy metal ions. They can be easily found and are a renewable source. Plant leaves are also non-toxic and biodegradable. After the biosorption process, they are expected to precipitate and become sediments which can be disposed safely. A research conducted by Salim and Abu El-Halawa (2002), used mulch plant leaves for the biosorption of cadmium, lead and copper ions. The results proved that the performance of the leaves is close to the efficiency of using activated carbon. The results also showed that oven-dried leaves have better performance compared to the naturally dried ones. The functional group which is commonly found in plant leaves is carboxylate\(^{10}\).

Available literature involving the use of mango leaf powder (MLP) for the biosorption of heavy metals is quite limited. Particularly, no study involving MLP for the removal of copper ions was found. One paper was found whose the researcher\(^{11}\) used several test plant materials including MLP as the biosorbents for the removal of lead ions\(^{36-41}\).

The maximum adsorption capacity for the MLP with lead was found to be 31.54 mg/g. Several researchers have also performed studies using different parts of the mango tree as biosorbents. One such study\(^{12}\) demonstrated the use of mango tree bark as biosorbents suitable for the removal of Hg\(^{2+}\) and Cr\(^{3+}\) from aqueous solutions.\(^{58}\)

**OBJECTIVES**

The main objective of this study is to evaluate the adsorption characteristics of Cu(II) from aqueous media using MLP. The adsorption will be carried out in a batch process, with varying adsorbent dosages, initial metal ion concentrations, initial pH of solution and operating temperature.

**MATERIAL AND METHODS**

**Preparation of biosorbent**

Mature and fresh mango leaves were collected from local trees and washed thoroughly by using distilled water to clean them from dirt and impurities. After that, the leaves were sun dried for a day on a perforated tray until the leaves turned brownish in colour. The leaves were then dried further in an oven (Memmert, DO6838, Germany) for 24 hours until the leaves became crisp. After drying, the leaves were ground by a mechanical grinder (Retsch-ZM 200), to constant size of 80µm and the resulting MLP was kept in a glass bottle ready for further experiments.

**Preparation of adsorbate**

The copper stock solution (1000mg/L) was prepared using analytical grades of Cu\(_2\)SO\(_4\)-5H\(_2\)O, which was purchased from HmbG Chemicals. Necessary dilutions were done to obtain 50mg/L, 75mg/L and 100mg/L of copper solution. Standard concentrations of 10, 20, 30 mg/L of Cu(II) solutions were also prepared for calibration purposes. The initial and final metal concentrations were analyzed via Atomic Absorption Spectrometer (AAnalyst 400 by Perkin Elmer) using the lamp at specific condition. The pH of the Cu(II) solution was adjusted by adding 0.1 M HCl or 0.1 M
NaOH and the measurement was done by pH meter (Martini instruments, Mi56P).

**Biosorption experiments**

The biosorption of Cu (II) from aqueous solution was investigated in batch biosorption experiments. The MLP with different dosages (0.4, 0.6, 0.8, 1.0 and 1.2 g/L) were added each in 5 conical flasks containing 100 mL of 100 mg/L Cu(II) solution. 1 mL of the Cu(II) solution was withdrawn by using a dropper and added in sampling tubes with scale that contained 9 mL of deionised water for the purpose of dilution. After that, the batch shake flask experiments were performed using a gyratory shaker (Protech, Model 903) with 75 rpm at 30°C for 3 hours. For the first hour, the samples were withdrawn every 15 minutes. For the following hours, the same procedure was repeated at every 30 minutes interval. The samples were tested for their Cu(II) ion concentration with the AAS.

For pH experiments, the pH of the solution was adjusted to 2.5, 4.5, 8.5 and 10.5 by using 0.1 M HCl and 0.1 M NaOH. Five different sets of experiments with variable concentration of Cu(II) solution, pH and temperature were performed. The operating parameters for each set of experiment are summarized in Table 1.

**Table 1 : Variation of experimental operating parameters**

The amount of material adsorbed per unit mass of adsorbent (mg/g) is given in equation (1):

\[
q = \frac{C_o - C_t}{m}
\]  

(1)

Where, \( C_o \) is the initial concentration of adsorbate (mg/L) and \( C_t \) is the concentration of adsorbate at time \( t \) (mg/L). The adsorption efficiency can be expressed as percentage adsorption of metal ion per equation (2):

\[
\% \text{ adsorption} = \frac{C_o - C_t}{C_o} \times 100\%
\]  

(2)

Where, \( C_o \) and \( C_t \) are the initial adsorbate concentration (mg/L) and the adsorbate concentration at time, \( t \) (min) respectively.
Equilibrium studies

Equilibrium data, commonly known as adsorption isotherms, are basic requirements for the design of adsorption systems. Classical adsorption models, Langmuir (1918) and Freundlich (1907), were used to describe the equilibrium between Cu(II) ions on the MLP at constant temperature.

The Langmuir equation is valid for a monolayer sorption on a homogenous surface with a finite number of identical sites and when there are no interactions between the sorbed species. The linear form of Langmuir equation is given in equation (3):

\[
\frac{C_e}{q_e} = \frac{1}{q_m} + \frac{1}{K_L q_m} C_e
\]  

where \( C_e \) (mg/L) is the equilibrium concentration of adsorbate, \( q_e \) (mg/g) is the quantity of adsorbed material (mg/g) at equilibrium, \( K_L \) is the Langmuir equilibrium constant related to the energy of sorption (L mg\(^{-1}\)) and \( q_m \) is the maximum amount of metal ions per unit weight of MLP to form a complete monolayer on the surface bound at high \( C_e \). It also represents a practical limiting adsorption capacity when the surface is fully covered with the metal ions and assists in the comparison of adsorption performance, particularly in cases where the sorbent did not reach its full saturation in experiments\(^{13-15}\).

The empirical Freundlich equation applies to multilayer sorption on a heterogeneous surface and can only be employed in the low intermediate concentration ranges. The Freundlich equation is given in equation (4):

\[
\log q_e = \frac{1}{n} \log C_e + \log K_f
\]  

where the \( K_f \) (mg g\(^{-1}\)) and \( n \) (value between 0 and 1) are the Freundlich constant characteristic on the system. \( K_f \) and \( n \) are indicators for adsorption capacity and adsorption intensity, respectively\(^{14,43-50}\).

RESULTS AND DISCUSSION

Effect of contact time

The effect of contact time was studied at different initial metal ion concentrations and MLP dosages. Fig. 1 shows the plot of adsorption efficiency against time for a fixed MLP dosage of 1.2 g/L, and varied metal concentration. It can be clearly observed that the percentage of adsorption generally increased until time reached 120 minutes. After this time, there was a drop in the adsorption percentage. Thus, 120 minutes was chosen as the optimum time where the adsorption reached equilibrium. The highest percentage of adsorption was found to be 22.68 %, 44.89 % and 54.99 % for concentration of 50 mg/L, 75 mg/L and 100 mg/L respectively. From the concentration experiments, 100 mg/L of Cu(II) was found to be optimal for the dosage of MLP used.

The relationship of adsorption efficiency with time at varied MLP dosages is depicted in Fig. 2. The results reveal a similar trend, where MLP removal is higher at the beginning (for the first 45 minutes) for all the dosages used.
This is due to the larger surface area of MLP available during the initial contact time. As the surface adsorption sites become exhausted, the uptake rate is controlled by the rate at which the adsorbate is transported from the exterior to the interior sites of the
adsorbent particles\textsuperscript{15-16}. Similar results were reported using wheat shell as the biosorbent\textsuperscript{17}.

Both figures show that the initial metal ion concentration and MLP dosage did not affect the time for the adsorption to reach its optimum time of 120 minutes. After the optimum time, both plots also showed a decrease in the removal efficiency. This indicates that desorption process may have occurred, as adsorption is a reversible process\textsuperscript{18,50-55}.

**Effect of biosorbent dosage**

The influence of the biosorbent dosage on the process was examined by using five different dosages at 0.4, 0.6, 0.8, 1.0 and 1.2 g/L. **Fig. 3** shows the relationship of metal uptake with the biosorbent dosage at Cu(II) concentration of 100 mg/L and time of 120 minutes.

![Plot of metal uptake, q against MLP dosage at 100 mg/L Cu(II) concentration at 30°C](image)

**Fig. 3**: Plot of metal uptake, q against MLP dosage at 100 mg/L Cu(II) concentration at 30°C

It can be observed that the increase in the biosorbent dosage causes decrease in the metal uptake. Similar results were also observed for Cu(II) concentrations of 50 mg/L and 75 mg/L. Vaghetti \textit{et al.} (2008)\textsuperscript{19} explained that this phenomenon is due to the splitting effect of flux (concentration gradient) between the adsorbate and biosorbent with increasing biomass concentration causing a decrease in amount of metallic ion adsorbed per gram of biomass. Another factor is that at high sorbent dosages, the available metal ions are insufficient to cover all the exchangeable sites on the biosorbent, usually resulting in a low metal uptake\textsuperscript{20}.

Besides, it might due to the formation of aggregation during biosorption causing a decrease in the effective adsorption area when the biomass concentration increases\textsuperscript{18,56}. Thus, it could be concluded that for this studies, the highest metal uptake occurs at the lowest biosorbent dosage (0.4
Effect of initial metal ion concentration

The initial metal ion concentration plays an important role towards the performance of a batch biosorption. The effect can be studied from the results of experiments at constant dosages of MLP. As shown in Fig. 4, the metal uptake of different dosages of MLP increased as the initial metal ion concentration increased from 50 to 100 mg/L, where the maximum value of metal uptake was observed to be from 14.78 mg/g to 206.85 mg/g respectively. These values were obtained at the optimum contact time of 120 minutes and MLP dosage of 0.4 g/L. The value of 206.85 mg/g is the maximum metal uptake, or the maximum adsorption capacity that was achieved by the biosorption of Cu(II) on MLP in this study. This observation was also in line with the research performed by two other researchers.21,22

According to Dang et al. (2008), this result is expected as the initial metal ion concentration functions as the driving force to overcome mass transfer resistances between the aqueous and solid phases. In addition, the increase in the initial metal ion concentration also increased the number of collisions between the metal ion and the biosorbent, hence increasing the metal uptake.23-57

Thus, it could be concluded that the highest metal uptake would occur at the highest metal concentration, which is 100 mg/L, at optimal conditions.

Effect of initial solution pH

The pH of the adsorbate solution is considered one of the most important factors affecting the biosorption process. This factor is capable of influencing not only the binding site dissociation state, but also the solution...
chemistry of the target metal in terms of hydrolysis, complexation by organic and/or inorganic ligands and redox potentials (Mack et al., 2007).

The range of pH tested in this experiment was from 2.5 to 6.5. Adsorption could not be carried out beyond pH 7 due to the precipitation of Cu(OH)$_2$. This is supported by several other studies$^{24-26}$. Solutions with pH lower than 2.5 was also not suitable as for these solutions, the surface active sites of the adsorbent would be protonated, resulting in a competition of Cu(II) and H$^+$ ions for the same surface active sites which would result in a low copper uptake$^4$.

In the present study, the pH was adjusted in the range of 2.5-6.5 by using dilute H$_2$SO$_4$ and 8-11 by using NaOH. The experiments were carried out at 100 mg/L of initial metal ion concentration with 0.4 g/L adsorbent dosage for an agitation time of 3 hours at 30°C. From Fig. 5, it can be observed that the adsorption is highest for pH 4.5 followed by pH 6.5 and 2.5.

These results were also presented in many previous studies which involved a maximum adsorption from pH 4.5 to 5.5$^{27,28}$. This trend was expected as at low pH values, most of the binding sites on the root surface would have positive charges making the binding and sorption of the metal ions unattractive to those sites$^{29}$.

![Fig. 5](image)

**Fig. 5**: Plot of adsorption efficiency against initial solution pH at 100 mg/L Cu(II) concentration, 0.4 g/L MLP at 30°C

The competition of Cu(II) with H$^+$ ions for appropriate sites on the adsorbent surface lowers the adsorption of Cu(II) ions. However, as the pH of the solution increases, this competition weakens, where Cu(II) ions replace H$^+$ ions bound to the adsorbent since increasing number of protons are dissociated from functional groups on the cell wall. In addition, at higher pH, there will be a change in the dominant functional groups responsible for binding on the cell wall, with carboxylate groups and diamine groups being the most important ones for pH < 5 and pH 6 respectively$^{30}$.
More negative groups were then made available on the adsorbent surface as pH increases.

The negatively charged adsorbent surface increased the electrostatic attraction between positively charged adsorbate and negatively charged adsorbent particles and therefore, leading to an increase in the adsorption of Cu(II) ions. However, further increase in the pH will cause the metals to form precipitates.

**Effect of temperature**

In order to examine the effect of temperature on copper biosorption, three different temperatures were selected. Experiments were carried out at 30°C, 45°C and 60°C. Based on Fig. 6, a clear trend can be observed. Temperature variation plays an important role on copper biosorption. The percentage of adsorption increases when the temperature increased.

This is more significant at low copper concentration of 50 mg/L with the highest increase in adsorption efficiency.

![Plot of adsorption efficiency against solution temperature with 0.4 g/L MLP](image)

**Fig. 6**: Plot of adsorption efficiency against solution temperature with 0.4 g/L MLP

This trend is also reported in studies such as by\(^{31}\), where biosorption of Pb (II) was carried out by fungus, *Cephalosporium aphidicola* and biosorption of copper, zinc and cadmium by dried seaweeds, *E. maxima* and *Laminaria pallida*\(^ {32}\). The increase of percentage of adsorption with temperature signifies the endothermic nature of the adsorption process. By increasing the temperature, the rate of diffusion will also increase and this leads to the diffusion of adsorbate molecules across the external boundary layer and in the internal pores of the adsorbent particle, owing to the decrease in the viscosity of the solution.

This enhancement was also reported due to the chemical interaction between adsorbates and adsorbent, creation of some new adsorption sites or the increased rate of
intraparticle diffusion of adsorbate molecules into the pores of the adsorbent at higher temperatures\textsuperscript{33}.

**Adsorption isotherms**

Many models have been proposed to explain adsorption equilibria, but the most important factor is to have applicability over the entire range of process conditions. The most widely used isotherms for solid-liquid adsorption are the Langmuir and Freundlich isotherms (Bulut and Tez, 2007). Both of these isotherms relate the adsorption density, $q_e$ (metal uptake per unit weight of adsorbent) to equilibrium adsorbate concentration in the bulk fluid phase, $C_e$\textsuperscript{34}.

Langmuir isotherm model is valid for monolayer adsorption onto a surface containing a finite number of identical sites. This isotherm is derived from the assumption that a maximum adsorption corresponds to a saturated monolayer of solute molecules on the adsorbent surface, with constant energy of adsorption, and no transmigration of adsorbate in the plane of the surface\textsuperscript{35}. The correlation coefficient that was obtained from the Langmuir plot as shown in Fig. 7 is 0.9984. However, the plot shows a decreasing trend, resulting in a negative gradient with a value of -0.0511. The maximum amount of metal ions per unit weight of MLP, $q_m$ was found to be -19.5695 while the Langmuir constant, $k_L$ is -0.00826. This trend is also observed for adsorption at different MLP dosages and initial metal ion concentration. These values prove that the adsorption is not favorable for a Langmuir isotherm, as they are supposed to be positive.

![Langmuir plot for adsorption of Cu(II) on MLP with dosage of 0.4 g/L and at 30ºC](image)

**Fig. 7**: Langmuir plot for adsorption of Cu(II) on MLP with dosage of 0.4 g/L and at 30ºC
Freundlich isotherm gives the relationship between the equilibrium liquid and solid phase capacity based on multilayer adsorption (heterogeneous surface). The Freundlich isotherm is based on the assumption that the adsorption sites are distributed exponentially with respect to the heat of 35. Based on Fig. 8, the correlation coefficient that was found from the Freundlich plot is 0.9775. This high value indicates that the adsorption is favorable for a Freundlich isotherm. In addition, the adsorption intensity, n, which was found to be 0.4761, further proves this finding. This is as this value is smaller than 1. Meanwhile, the Freundlich constant, K_F was found to be 0.004156. These results also indicate that the MLP surface is heterogenous in the long range, but may have short range of uniformity 36.

**Fig. 8**: Freundlich plot for adsorption of Cu(II) on MLP with dosage 0.4 g/L and at 30°C

**Performance of MLP when compared to other biosorbents**

From the studies carried out, it was found that MLP appears to be a promising adsorbent for the effective removal of Cu(II) metal ions from wastewater. Table 2 below gives a comparison of MLP with other types of biosorbents.
### Table 2: Performance of MLP when compared to other biosorbents

**CONCLUSION**

The following conclusions can be drawn based on the investigation of Cu(II) adsorption by MLP:

1. The optimum contact time for the maximum adsorption capacity of Cu(II) on MLP was 120 minutes.
2. The metal uptake of Cu(II) on MLP decreased with increasing MLP dosage.
3. The metal uptake and adsorption efficiency of Cu(II) on MLP increased with increasing metal ion concentration.
4. The maximum adsorption capacity of Cu(II) on MLP was 206.85 mg/g which was obtained with 0.4 g/L MLP dosage, 100 mg/L Cu(II) concentration and a pH of 4.5.
5. Higher adsorption efficiency of Cu(II) on MLP was observed at higher temperatures.
6. The experimental data for the adsorption of Cu(II) on MLP fits well for the Freundlich isotherm.
