Networks of nonlinear resonators offer intriguing perspectives as quantum simulators for nonequilibrium many-body phases of driven-dissipative systems. Here, we employ photon correlation measurements to study the radiation fields emitted from a system of two superconducting resonators in a driven-dissipative regime, coupled nonlinearly by a superconducting quantum interference device, with cross-Kerr interactions dominating over on-site Kerr interactions. We apply a parametrically modulated magnetic flux to control the linear photon hopping rate between the two resonators and its ratio with the cross-Kerr rate. When increasing the hopping rate, we observe a crossover from an ordered to a delocalized state of photons. The presented coupling scheme is intrinsically robust to frequency disorder and may therefore prove useful for realizing larger-scale resonator arrays.

Engineering optical nonlinearities that are appreciable on the single photon level and lead to nonclassical light fields has been a central objective for the study of light-matter interaction in quantum optics [1–3]. While such nonlinearities have first been realized in individual optical cavities [4,5] and with Rydberg atoms [6,7], more recently superconducting circuit quantum electrodynamics (QED) [8] has proven to be a powerful platform for the study of nonclassical light fields. Circuit QED systems facilitate strong effective interactions between individual photons [9,10], long coherence times [11], as well as precise control of drive fields [12,13] within a large variety of possible design implementations. Particularly, in situ tunable or nonlinear couplers have been explored more recently for superconducting elements [14–21].

Well-controllable engineered quantum systems offer interesting perspectives to study interacting many-body systems with photons [22–24]. Interacting photons are typically explored in a nonequilibrium regime, in which continuous driving compensates for excitation loss and yields stationary states of light fields [25].

Nonequilibrium coupled resonator systems have been investigated experimentally, both in a semiclassical and in a quantum regime. Macroscopic self-trapping of exciton polaritons has been observed in a dimer of coupled Bragg stack microcavities [26], vacuum squeezing was demonstrated in a dimer of superconducting resonators [27], the unconventional photon blockade has been observed in the microwave and the optical domain [28,29], and signatures of bistability have been found in a chain of superconducting resonators [30]. Moreover, a transition from a classical to a quantum regime has been observed in the decay dynamics of a resonator dimer [31], chiral currents of one or two photons have been generated in a three qubit ring [32], and spectral signatures of many-body localization [33] as well as a Mott insulator of photons [34] have been observed in a qubit chain.

In this Letter, we explore the interaction between individual photons in a driven-dissipative system of two nonlinearly coupled superconducting resonators [see Fig. 1(a)]. The nonlinear coupler mediates a cross-Kerr interaction \( V \), on-site Kerr interactions \( U_a \) and \( U_b \), and an effective linear hopping interaction with in situ tunable rate \( J_{ac} \). Our experiment provides a realization of a steady state quantum system, in which cross-Kerr interactions exceed local Kerr interactions, meaning that the force between particles grows as they are separated and only starts to decay once the separation exceeds the lattice constant. We measure the on-site \( g_{ia}^{(2)}(\tau = 0) \) and \( g_{ab}^{(2)}(\tau = 0) \) between the emitted field from both resonators.

In the limit of small \( J_{ac}/V \), a photon trapped in one resonator blocks the excitation of the neighboring resonator and vice versa, leading to a spontaneous self-ordering of microwave photons [35,36]. Such an intersite photon blockade regime has been predicted for resonator arrays with nonlinear couplers [37,38]. When increasing \( J_{ac}/V \), however, a delocalization of photons and a simultaneous occupation of both resonators becomes favorable, leading to a change in the photon statistics.

For this experiment we utilize an on-chip superconducting circuit consisting of two lumped element resonators with characteristic impedance \( Z = 80 \Omega \) [see Figs. 1(b),1(c)]. The aforementioned nonlinear coupling circuit, interconnecting...
mitted amplitude $j$ of the intracavity field is emitted and measured using a and to an output port (1 and 2) into which approximately input port (3 and 4), through which we drive the system, the SQUID loop. Each resonator is weakly coupled to an ensure full dc and ac control of the magnetic flux threading the conducting coil and an on-chip flux drive line (port 5) to 80 GHz, with the Planck constant $\hbar$.

The flux dependence of the measured eigenfrequencies is well explained by a linear circuit impedance comprising a tunable effective Josephson energy, allowing us to determine the aforementioned circuit parameters. From a normal mode model we extract the tuning range of the corresponding linear hopping rate $J_{ac}/2\pi = -0.8...0.8$ GHz [Fig. 2(b)]. The tunability of $J_{dc}$ results from an interplay between the capacitive and the flux-dependent inductive coupling between the two resonators. As these carry opposite signs, we are able to cancel both contributions achieving approximately zero net static linear coupling $J_{dc} \approx 0$ at a dc flux bias point of $\Phi_{dc} \approx -0.37\Phi_0$, where $\Phi_0 = h/2e$ is the magnetic flux quantum. At this bias point the two measured resonances ($\omega_a, \omega_b$) are separated by the bare detuning $\Delta/2\pi = (\omega_b - \omega_a)/2\pi = 362$ MHz and correspond closely to the local modes of the system [Figs. 2(c),2(d)]. As a result, the radiation of each mode ($a, b$) is collected in its respective output line at port (1, 2). Notably, the finite detuning $\Delta$ between the bare cavity modes suppresses undesired nonlinear interactions, which would otherwise give rise to pair hopping and correlated hopping and disrupt the scope of the experiment (see Supplemental Material [39]).

In order to recover a well-controllable linear hopping rate despite the finite cavity detuning, we implement a parametric coupling scheme [14,19,43]. Here, we apply an ac modulated flux drive to the SQUID with a variable amplitude $\Phi_{ac}$ and a modulation frequency $\omega_{ac}$, which equals the resonator detuning $\omega_{ac} = \Delta$. For $\Phi_{ac} = 0$ we recover the uncoupled resonator modes when probing the transmission spectra $|S_{11}|$ and $|S_{22}|$ [see Fig. 3(a)]. However, as we increase $\Phi_{ac}$, we observe a simultaneous frequency splitting of both modes, which scales linearly with $\Phi_{ac}$, and which we interpret as the result of a parametrically induced photon hopping with rate $J_{ac}/2\pi = 0...40$ MHz (see Supplemental Material [39]).

In an appropriate doubly rotating frame, where each mode rotates at its resonance frequency, our system is well described by an effective Hamiltonian.

FIG. 1. (a) Sketch of an optical analogue of the setup, consisting of two resonator modes $a$ and $b$ with Kerr nonlinearities $U_a$ and $U_b$, coupled via a cross-Kerr interaction $V$ and a tunable linear hopping rate $J_{ac}$. (b) Equivalent circuit diagram and (c) false-colored micrograph of the sample, featuring two lumped-element $LC$ resonators $a$, $b$ (blue, red), coupled via a nonlinear coupling element composed of a capacitor and a SQUID (inset). The resonators are accessed via two symmetric sets of weakly coupled input lines (yellow, ports 3 and 4) and output lines (green, ports 1 and 2). A flux modulation tone is applied via a dedicated $T$-shaped flux line (purple, port 5).

FIG. 2. (a) Measured transmission amplitude $|S_{21}|$ vs magnetic flux $\Phi_{dc}$ and fit of the resonance frequencies to a linear circuit impedance model (thin orange line). The working point $J_{dc} = 0$ is indicated by a dashed orange line. (b) Linear hopping rate $J_{ac}$ vs $\Phi_{ac}$, calculated using a normal mode model based on the circuit parameters extracted from (a). (c),(d) Reflection coefficient measurements of bare cavity modes at $\Phi_{dc} \approx -0.37\Phi_0$ ($J_{ac} \approx 0$) with fit to a Lorentzian (solid filling).
correspond to the photon number states metric modulation the eigenstates of this Hamiltonian Supplemental Material [39]). In the absence of a para-

difference \[ \Delta \] for varying flux modulation amplitude \( \Phi_{ac} \) applied to port 5. Linear fits to the resonance frequencies of the \( J_{ac} \)-hybridized modes are shown as black dashed lines. (b) Energy level diagram for vanishing (gray box) and finite linear hopping rate \( J_{ac} \) via parametric modulation at the frequency difference \( \Delta = \omega_a - \omega_c \). (c) Energy levels of resonator \( b \) in the first (purple) and second (orange) excitation manifold vs \( J_{ac} \).

\[
\frac{1}{\hbar} \mathcal{H}_\Delta = \delta_a a^\dagger a + \delta_b b^\dagger b + J_{ac}(a^\dagger b + b^\dagger a) 
+ \frac{1}{2} U_a a^\dagger a^2 + \frac{1}{2} U_b b^\dagger b^2 + V a^\dagger a b^\dagger b 
+ \Omega_a(a^\dagger a) + \Omega_b(b^\dagger b),
\]

with the drive detuning \( \delta_i = \omega_{\text{drive},i} - \omega_i \) \((i \in \{a, b\})\) and the drive rates \( \Omega_i \). The on-site and the cross-Kerr interaction rates at zero coupling bias are \((U_a, U_b, V)/2\pi = -(3.1 \pm 0.3, 2.7 \pm 0.2, 7.0 \pm 0.3)\) MHz, which have been extracted from a spectroscopic measurement (see Supplemental Material [39]). In the absence of a parametric modulation the eigenstates of this Hamiltonian correspond to the photon number states \( |n_a, n_b\rangle \) in the local basis [compare Fig. 3(b)]. The second order transitions are redshifted by the corresponding Kerr rates. For finite \( J_{ac} \) the eigenstates hybridize in both the one- and two-photon manifold.

We focus on a parameter regime in which \( |V| \) and \( J_{ac} \), as well as \( \kappa_i \) and \( \Omega_i \), are comparable in magnitude, featuring a competition between nonlinear interaction and linear hopping, as well as between drive and dissipation. In our system we additionally have \( |U_i| \approx \kappa_i \). Both \( \Omega_a = \Omega_b = \Omega \), setting the average number of excitations in the system, and \( J_{ac} \), setting the rate at which the resonators exchange excitations, are utilized as tunable control parameters, while \( V, U_i \), and \( \kappa_i \) are constant. In the experiment we keep the drive frequencies, and thus \( \delta_i = 0 \), fixed. We eliminate influences of the phase of \( J_{ac} \) on the measured results by averaging over multiple randomized phase configurations.

We characterize the quantum states of the uniformly and continuously driven two-resonator system by measuring the second order cross \( g_{ab}^{(2)} \) and on-site correlation \( g_{aa}^{(2)} \) of the emitted radiation as a function of \( J_{ac} \) and \( \Omega \) [see Figs. 4(a), 4(c)]. To this aim, we linearly amplify and digitize the radiation fields at both output ports in order to obtain the second order photon correlations [27,44,45].

Corresponding results from numerical simulations. (e) \( g_{ab}^{(2)} \) vs \( J_{ac} \), cut for \( \Omega/2\pi = 0.76 \) MHz (see black dashed line; measured data are shown with markers, numerical simulations with black dotted line). (f) \( g_{ab}^{(2)} \) vs \( \Omega \), cut for \( J_{ac}/2\pi = 0 \) MHz (see black dotted line).

To enhance the signal-to-noise ratio, we use a quantum-limited Josephson parametric amplifier [27] operated in a phase-sensitive mode (see Supplemental Material [39] for details about the detection process). The measured \( g_{ab}^{(2)} \) correlations are compared with the results of a numerical master equation simulation [46] [see Figs. 4(b), 4(d)]. As confirmed by this simulation, the average resonator occupations remain at or below the single photon level for all the data presented in Fig. 4.
In the regime of small $J_{ac}$ and low $\Omega$ we measure the radiation to be antibunched, see Fig. 4. In this limit, the cross-Kerr interaction effectively shifts the transition frequency of one cavity when a photon is present in the other and thus detunes the $(|01\rangle, |10\rangle \leftrightarrow |11\rangle)$ transition from the drive tones. This inhibits simultaneous occupation of both cavities, leading to a dynamic self-ordered photon state manifested as antibunching in the photon cross statistics. We thus observe the finite lattice size version of the spontaneous breaking of the symmetry between the two cases of only even or only odd lattice sites being occupied [37,47]. Equivalently, the on-site Kerr interaction prevents each mode from being doubly excited, leading to antibunched on-site correlations.

Increasing the hopping rate $J_{ac}$ results in a hybridization of the modes in both the one- and two-excitation manifold; see Fig. 3(c) for a level diagram as a function of $J_{ac}$. When $J_{ac}$ becomes comparable to the Kerr rate $|U_i|$, the transitions to the single photon manifold become detuned from the drive frequency, while the two-photon transition to the symmetric $(|02 + 20 + 11\rangle$ branch becomes resonant with the drive. This leads to a more efficient drive into the second excitation manifold compared to the originally dominant single photon states and to an admixture of the drive tones. This causes a crossover from antibunched to bunched statistics in both the measured $g^{(2)}_{ab}$ and $g^{(2)}_{ia}$, see Fig. 4(e). Interestingly, we find a regime in which the on-site correlation $g^{(2)}_{ia}$ is already close to unity, while the cross-correlation $g^{(2)}_{ab}$ is still antibunched. We attribute this effect to $|V|$ being larger than $|U_i|$. Whereas the observed anticorrelated $g^{(2)}_{ab}$ functions are expected to persist for larger lattices, the bunching at large linear coupling is a finite size effect as no spectrally dense single excitation band forms for two resonators.

Studying the dependence on the drive rate $\Omega$, we find that $g^{(2)}_{ia}$ approaches unity when $\Omega$ exceeds $|U_i|$ [Fig. 4(f)], which we explain by the breakdown of the photon blockade. This effect is found to be largely independent of $J_{ac}$. We observe a similar behavior for the cross-correlations. In this case, however, the measured $g^{(2)}_{ab}$ approaches one-half in the limit of large drive rate $\Omega$, which is in good agreement with the result obtained from the numerical simulations.

In conclusion, we have realized a coupled cavity system, featuring a tunable ratio between linear hopping and cross-Kerr interaction rate and observed the crossover from photon ordering to delocalization. Inspired by the proposals by Jin et al. [37,38], we interpret the measured cross correlations as an order parameter in a $(J_{ac}, \Omega)$-dependent phase diagram of the system. The observed crossover closely resembles the onset of a driven-dissipative photon ordering phase transition, from a fully ordered crystalline phase dominated by spontaneous symmetry breaking towards a uniform delocalized steady-state phase [48,49].

As such, we demonstrated the feasibility to measure and control nonequilibrium quantum many-body phenomena using interacting photons in engineered quantum systems [50]. Such strongly correlated photonic systems may prove particularly useful as a tool for analog quantum simulation [51-54], where the active control of extended quantum states may be used to emulate other less accessible quantum systems, with the prospect of complementing theoretical and numerical studies in gaining insights on exotic quantum phenomena [55-59].

We expect the demonstrated coupling mechanism to be well extendable towards larger resonator arrays. Resilience to disorder in electrical parameters [60] and suppression of potential crosstalk can be achieved by frequency staggering of neighboring cavities along with the adjustability of the parametric modulation frequencies. Additionally, the employed lumped element structures excel in this scenario thanks to a compact footprint and high design versatility.

The presented system and variations thereof could be used to explore regimes in which intersite interactions exceed on-site interactions [61,62]. Additionally, the controllability of the phase of the hopping rate could be employed to create artificial gauge fields in plaquette systems and to study nonreciprocal dynamics with photons [32]. Furthermore, the variability of flux modulation frequencies could enable the controllable activation of additional interaction terms such as a parametric coupling between neighboring resonators [63] or pair hopping [64], e.g., for the study of supersolid phases [65,66].
