Keywords fiducial marker, photogrammetry, European sea bass, regional convolutional neural network, CNN, videogrammetry

Summary

1 An image can encode date-time, location and camera information as metadata and implicitly encodes species information and data on human activity, e.g. the size distribution of fish removals. Accurate length estimates can be made from images using a fiducial marker however, their manual extraction is time consuming and estimates are inaccurate without control over the imaging system. This article presents a methodology which uses machine vision to estimate the total length (TL) of a fusiform fish (European sea bass).

2 Three regional convolutional neural networks (R-CNN) were trained from public images. Images of European sea bass were captured with a fiducial marker with 3 non-specialist cameras. Images were undistorted using the intrinsic lens properties calculated for the camera in OpenCV, then TL was estimated using machine vision (MV) to detect both marker and subject. MV performance was evaluated for the three R-CNNs under downsampling and rotation of the captured images.

3 Each R-CNN accurately predicted the location of fish in test images (mean intersection over union, 93%) and estimates of TL were accurate, with percent mean bias error (%MBE [95% CIs]) = 2.2% [2.0, 2.4]). Detections were robust to horizontal flipping and downsampling. TL estimates at absolute image rotations > 20° became increasingly inaccurate but %MBE [95% CIs] was reduced to -0.1% [-0.2, 0.1] using machine learning to remove outliers and model bias.

4 Machine vision can classify and derive measurements of species from images without specialist equipment. It is anticipated that ecological researchers and managers will make increasing use of MV where image data is collected (e.g. in remote electronic monitoring, virtual observations, wildlife surveys and

morphometrics) and MV will be of particular utility where large volumes of image data will be gathered.

1 Introduction

Currently only a small proportion of the world's marine stocks are sufficiently data rich to enable formal stock assessments to be performed, hence most marine fisheries are data poor (Costello et al., 2012; Ricard et al., 2012). This is in spite of legislation (e.g. European Commission Decision 2008/56/EC) which requires marine stocks to be exploited sustainably and managed with consideration of their associated ecosystems. The potential for commercial fisheries to negatively impact stocks and ecosystems is accepted, but recreational fishing can also negatively impact fisheries and associated ecosystems (reviews Lewin et al., 2006; Radford et al., 2018). Marine recreational fisheries in particular can lack current and historical data even in developed countries and monitoring of the sector is poor (ICES, 2017; Hyder et al., 2018).

Fisheries assessments have survey phases in which a metrological measurement of the target species occurs (National Research Council, 2006; ICES, 2012). In both commercial and recreational fisheries, measurement has traditionally involved observations by researchers, fisheries managers or the fishers themselves. Observer costs are high in commercial monitoring (e.g. Needle et al., 2015) and in the assessment of recreational fisheries (pers. observ. KH). Hence, there has been an increasing interest in remote electronic monitoring (REM) (e.g. White et al., 2006, Chang et al., 2010, Hold et al., 2015, Bartholomew et al., 2018). Videogrammetry and photogrammetry (hereafter, photogrammetry) are becoming increasingly commonplace in non-destructive observational marine research (e.g. Dunbrack, 2006, Deakos, 2010).

The use of REM and related approaches is likely to increase as camera technology improves and equipment costs fall (reviews Struthers et al., 2015, Bicknell et al., 2016). Photogrammetry can provide considerable savings when compared to observers (Chang et al., 2010; National

79 Oceanic and Atmospheric Administration, 2015). Capturing images produces vast volumes of
80 data which is time consuming to process (e.g. Needle et al., 2015, van Helmond et al., 2017).
81 This problem can be alleviated by using motion detection algorithm(s) to extract salient frames
82 from videos (e.g. Weinstein, 2015), but the extracted frames still require manual processing.
83 Object detection with machine vision (MV) could be used to automate the extraction of data
84 from images. Historically, MV has been used to analyse images which have been captured
85 under controlled conditions (e.g. fixed cameras, backgrounds and lighting). This control makes
86 the isolation of the subject from the background (segmentation) much easier, allowing
87 computationally inexpensive techniques to be applied, e.g. using optical flow (Zion et al., 2007;
88 Spampinato et al., 2010; Hsiao et al., 2014) and segmentation by pixel properties (e.g. White
89 et al., 2006, Jeong et al., 2013).
90 To date, photogrammetry has typically used multi-laser (e.g. Deakos, 2010, Bartholomew et
91 al., 2018) or multi-camera systems (e.g. Dunbrack, 2006, Rosen et al., 2013, Neuswanger et
92 al., 2016), but the equipment is comparatively bulky and expensive. Single camera systems and
93 a fiducial marker (i.e. an object of known scale placed in the camera's field of view) have been
94 used (Hold et al., 2015; van Helmond et al., 2017) but control of the camera model or the
95 framing of the fiducial marker and subject is usually required (e.g. Rogers, Cambiè, & Kaiser,
96 2017). Without this control, length estimates are subject to an unknown error because lenses
97 have different optical properties. The additional challenges in extracting quantitative data from
98 images taken by volunteers—or other scenarios where expensive or less portable equipment is
99 unsuitable—may explain the almost complete lack of a suitable solution. Convolution neural
100 networks (CNN) currently outperform all other methods at object detection and CNN
101 application programming interfaces (API) are now mature and stable enough to be viable
102 solutions for (merely) competent programmers to use regional CNNs (R-CNN) for object
103 detection.

This article explores the feasibility of using MV to automate the identification and size estimation of an important species from images. The objectives are to (i) introduce the software and methods to achieve length estimation with a cheap and portable fiducial marker; (ii) to show that length estimates can be made with no control over the image background, lighting or specialist cameras using a foreground fiducial marker; (iii) provide region of interest (RoI) labelled images of the European sea bass, *Dicentrarchus labrax* (see Appendix S2 Supporting Information); (iv) to compare the speed and performance of three state-of-the-art R-CNN networks.

2 Methods[1]

2.1 Ethics

European sea bass captures were made by recreational fishers and a commercial vessel as part of their day-to-day activity. All reasonable measures were taken to minimise air exposure time to the fish while photographs were taken. Ethical approval was granted by the Animal Welfare and Ethical Review Board of Bangor University, Wales, UK.

2.2 Training and validation image acquisition

Training ($n = 734$) and validation ($n = 184$) images were obtained from online public sources. The RoI for each image was drawn tight to the fish body, to the limits of the caudal fin tips and the snout vertex (Fig. 1a). Training and inference were carried out in Tensorflow (Google, 2018) using transfer learning with the following pretrained R-CNNs; (i) ResNet-101 (He et al., 2016), (ii) Single shot MobileNet detector (Howard et al., 2017) and (iii) NASNet (Zoph & Le, 2017), abbrevs. ResNet, MobileNet and NASNet respectively.

[1] Appendix S1 Supporting Information contains additional methodological detail.

2.3 Fiducial marker selection and image acquisition

Three ArUco fiducial markers (Garrido-Jurado et al., 2014) of side lengths 25 mm, 30 mm and 50 mm were mounted on polypropylene sheets (Fig. 1b). Photographs of European sea bass were taken on the shore and afloat, with the informed consent of fishers and with 3 different non-specialist cameras (henceforth *marker images*). Fish were posed to minimise body distortion and occlusion. Fish total length (TL) was measured and recorded. The marker was placed on the fish (Fig. 1c) and then photographed.

2.4 Undistorting marker images

Images from each camera were corrected for radial and tangential distortion with the OpenCV API (OpenCV team, 2018). Lens calibration profiles were created in OpenCV for each camera at each supported field of view and focal length (henceforth *undistorted images*).

2.5 Length estimation

An R-CNN predicts the rectangle which most accurately bounds the subject within the image and then defines the detection as a rectangle defined by four vertices. Intersection over Union (IoU) measures the accuracy of object localisation by comparing the area of a manually defined ground truth rectangle which bounds the subject with the bounding rectangle predicted by the R-CNN. Each model outputs an objectness score (*score*) which is interpreted as the probability that the proposed region contains the predicted class (Ren et al., 2017).

When estimating TL, the pixel length of the long side of the detection rectangle approximates to the TL (pixels) of the fish. The real-world length per pixel, $\bar{l}$ was estimated from the four sides of the detected ArUco marker according to, $\bar{l} = \frac{1}{n} \cdot \sum_1^n l/p_i$ where p_i is the i^{th} side length in pixels, and l is the real-world side length (e.g. 50 mm). The accuracy of $\bar{l}$ was validated manually (Linear Regression, b = 1.003, R^2 = 0.999) using ImageJ (Schneider et al., 2012). Mean absolute error (MAE) and mean bias error (MBE) are reported and are calculated as

follows, $MAE = \frac{1}{n} \cdot \sum_{i=1}^{n} |l_i - \widehat{l_i}|$ and $MBE = \frac{1}{n} \cdot \sum_{i=1}^{n} l_i - \widehat{l_i}$ where l_i is the i^{th} estimate of TL and $\hat{y}_i$ is the expected (i.e. actual) TL of the i^{th} element. Hence a negative bias represents an underestimate of TL.

2.6 Detection and length estimation with rotation, flipping and downsampling

The accuracy of TL estimates under three translations were checked, these were; (i) image rotation between -30° and 30° in increments of 1°; (ii) horizontal flipping of the image by the x-axis, i.e. the line $x = 0.5 \cdot width$; and (iii) image downsampling by a factor of 1.5, to a minimum image height or width of 50 pixels. TL estimates for rotated images were corrected based on the geometry of the detection box under increasing rotation in relation to the snout and caudal vertices of the subject.

2.7 Removing outliers and modelling bias

NASNet R-CNN detections were split into training and test data. Training data were used to identify biased outliers using an isolation forest (Liu et al., 2008; Pedregosa et al., 2011) with the variables; (i) ratio of height to width of the detection, (ii) objectness score and (iii) % MBE. Outliers were then removed from the training set and a gradient boost regressor (Friedman, 2002; Pedregosa et al., 2011) trained on the predictors (i) and (ii) above. Outliers were removed from the test dataset and the gradient boost regressor model used to correct bias. Further methodological details are given in Appendix S3 Supporting Information.

Several estimates of length measurements are reported and are listed in Table 1. Means followed by square brackets or the ± notation indicate 95% confidence intervals or standard deviation respectively.

3 Results

For every non-transformed European sea bass image, each CNN generated region proposals with objectness scores > 0.5 (with the exception of a single MobileNet score of 0.01). All

regional proposals were at least partially coincident with ground truth, with a minimum IoU of 45% (45% IoU detection shown in Fig. 1b). Negative images had no false detections under any network (score mean of 0.005 ±0.008, n = 30, max = 0.04).

Detection performance between networks was practically indistinguishable on untransformed and horizontally flipped images (Table 2), hence detections were invariant to horizontal flipping (IoU mean; horizontal flip, 93.2% [93.0, 93.4]; untransformed, 92.8% [92.5, 93.0]). This equivalence is despite the large differences in mean detection times (Table 2). Nonetheless, when visualised it is apparent that the NASNet network delivered more consistent object detections with no IoU outliers (Fig. 2). All single MobileNet detections had IoUs > 75% however, ResNet had 7 detections < 75% IoU (1.1% of all detections).

3.1 Length estimates

ArUco markers were consistently recognised using the OpenCV API under natural conditions, with the marker successfully localised in 99.3% of untransformed images. Two detection failures occurred because of over-exposure (Fig. 1e). *Corrected MV-TL* estimates had a MBE of 5.9 mm ±20, compared with MBE derived from *corrected manual-TL* estimation of -0.5 mm ±14.8. C*orrected MV-TL* estimates showed consistent variance in bias across *physical TL* (Fig. 3). On excluding TL estimates made under the noisier ResNet and MobileNet networks, MBE for *corrected MV-TL* estimates was increased by 2 mm to 7.9 mm nevertheless, S.D. decreased to 14.7 mm, matching the precision of manual estimates of TL (*corrected manual-TL*).

Corrected manual-TL and *MV-TL* estimation errors tended to be less accurate and precise (mean squared error, MSE) when made on the shore rather than afloat (Fig. 4, MSE; Afloat, 7.9; Shore, 25.9), and there was no apparent systematic bias in length estimation introduced by the camera model when comparing *corrected manual-TL* estimates (which have lower variance than MV-TL length estimates) with platform as a covariate (ANCOVA, $F_{(2, 1787)}$, p = 0.15).

198 Mean %MBE for *corrected manual-TL* estimates were 0.7% ±4.6, 1.1% ±4.0 and 0.7% ±4.1
199 for the GoPro Hero 5 action camera, Samsung s5690 smartphone and Fujifilm XP30 camera
200 respectively.

201 The increased %IoU outliers observed during detection with ResNet and—to a lesser
202 degree—the MobileNet single shot detector manifest as the %MBE outliers in Fig. 4. The
203 ResNet detector produced 9 of the top 10 MV associated underestimates (fully corrected
204 percent errors of -16.4% to -38.0%). These errors arose because detections followed the
205 approximate pattern observed in (Fig. 1d), with the ResNet detector occasionally truncating the
206 detection. This behaviour was not observed in the other detectors on untransformed images
207 (i.e. an image which has not been flipped, downsampled or rotated).

208 **3.2 Scale**

209 ArUco marker detection was robust to downsampling to approximately 30% of the original
210 image size (original image size, mean = 1355 by 1029 pixels, or 1.5M pixels^2). ArUco markers
211 were approximately 18 pixels^2 at 30% of original image size and images were approximately
212 400 by 300 pixels (120k pixels^2). At 30% image size the marker detection rate was 93%
213 however, this dropped to 53% at the next scaling factor of 20% (Table 3). The networks on
214 average, maintained objectiveness scores of ~98% at the 20% scaling factor, where the mean
215 image size was 41.4k pixels^2 (i.e. ~203 pixels^2). At this image size, the average ground truth
216 RoI was 158 by 23 pixels. NASNet produced marginally more accurate TL estimates under
217 downsampling. For each network %MAE increased in increments of between 1% and 2% until
218 the downsampling factor exceeded ~30% (mean ground truth width = 238 pixels), after which
219 %MAE began to increase in larger increments. Each network responded similarly to
220 downsampling (Fig. 5), at 20% image size, %MAE = 9.9% ±7.8 which increased markedly to
221 15.9% ±8.4 at 13% of the original image size at ~153 pixels^2.

3.3 Rotation

The NASNet and ResNet networks behaved similarly under image rotation (Fig. 6) and detection was robust to small rotations, with over 90% of objectiveness scores greater than 50% at absolute rotation ≤ 20% for the NASNet and ResNet networks. At 20° absolute rotation the MobileNet network had 67% of objectiveness scores below 50%. As the absolute rotation angle increased beyond ~15°, NASNet and ResNet predictions of *corrected MV-TL* exceeded 5% %MBE however, %MBE was 2.5% for the MobileNet network (Fig. 6, absolute rotation = 15°, %MBE; NASNet, -5.0% [-5.3, -4.6]; ResNet, -5.3% [-5.9, -4.7]; MobileNet, 2.7% [2.2, 3.3]). This apparently good performance of the MobileNet CNN masks the greatly decreased confidence in regional proposals under this network (score series, Fig. 6) and a corresponding loss of valid detections.

The geometric rotation correction (variable *rotation corrected MV-TL*) did not consistently decrease bias for all rotations (see Appendix S1 Supporting Information) and bias reduction was only marginally improved for the NASNet and ResNet networks (1.2% and 0.5% respectively) however, bias was increased for the MobileNet network (1.0%). The NASNet and ResNet networks displayed a consistent hyperbolic pattern in TL estimation bias through the rotation range and prediction error was consistent across rotations (Fig. 6).

Combining outlier removal and adjusting *rotation corrected MV-TL* per sample with the trained gradient descent regressor model produced a marked reduction in %MBE across rotations. This correction centred bias at ~0% for absolute rotations ≤ 20° (Fig. 7; Table 4). The overall improvement on applying all corrections to MV estimates following lens correction only are unambiguous, with unadjusted *MV-TL* estimates of %MBE = -11.4% [-11.6, -11.2].

4 Discussion

This study introduced a methodology to estimate fish TL—a crucial measurement in multiple stock assessment methods (Pauly & Morgan, 1987)—using recent advances in open-source

R-CNNs and associated software applications (e.g. Abadi et al., 2015, OpenCV, 2018). By using these resources, it was shown that the position of an organism in an image could be accurately predicted without strict control over lighting conditions or subject background. The high degree of accuracy of the predicted RoI (> 90% IoU) enabled the accurate estimation of TL. TL estimation was achieved without reliance on specialist cameras, multi-camera systems (e.g. Dunbrack, 2006; Rosen et al., 2013) or paired lasers (e.g. Deakos, 2010, Rogers et al., 2017).

Photographing a well-posed subject with a foreground fiducial marker is faster and more convenient than measuring and recording the subject length manually (pers. observ.). Possessing photographs of subjects provides a persistent record which can be used to derive additional measurements, to cross check data and for validation by third parties. In volunteer based research (e.g. diary surveys) additional data are typically required by research programmes (e.g. GPS position, date/time, species) and these data can be automatically captured at image acquisition. The potential for automatic recording of much of the required data—including the onerous task of physically recording a dimension—reduces the recording burden on volunteers which can improve participant retention, the volume of data submissions and data quality as observed in surveys (Galesic, 2006; Hoerger, 2010).

4.1 Networks

Of the three networks, NASNet outperformed the ResNet-101 and MobileNet networks. NASNet was particularly effective at limiting outlier detections. However, the NASNet network had the slowest detection speeds of the three and was the most resource intensive. During learning, NASNet had to be limited to a batch size of 1 to fit within the 6 Gb of memory of the NVIDIA 1060 GTX card (configuration files are available in the Supporting Information). This is unsurprising as the NASNet has many more parameters than ResNet (Zoph & Le, 2017).

Neither ResNet nor NASNet are currently capable of performing real-time detections however, MobileNet can be deployed on mobile devices. The performance of MobileNet in this task was arguably better than ResNet and real time detection would be of particular benefit in volunteer based data collection applications where users could be given immediate feedback on the success or failure of a particular recognition task (e.g. Kumar et al., 2012, Fishbrain, 2018, International Game Fish Association, 2018, Stowell, 2018).

4.2 Length estimation

The standard fish length measurements (TL, fork length FL and standard length SL) are particularly suited to estimation by R-CNN based networks because the longitudinal dimension of an ideal detection corresponds with the distal extremes of the morphological features which delineate these lengths. In this manuscript, TL was used to demonstrate the methodology, but other measurements (including FL and SL) may be estimated by changing the RoIs defined in the training and test images or using previously determined morphometric relationships (e.g. Needle et al., 2015). To date, rectangular ROIs—the detection outputs of R-CNNs—have no history of providing length data in fisheries assessments because R-CNNs are a recent development in MV. However, our results demonstrate the accuracy which can be achieved where body distortion can be controlled.

Where curvature of the subject body cannot be controlled, lengths have been estimated by identifying depth midpoints and calculating the line bisecting these midpoints (Strachan, 1993; White et al., 2006) or line fitting to subject contours (Miranda & Romero, 2017). Both approaches require accurate segmentation of the subject from the background, which is problematic in uncontrolled environments. Nevertheless, Tensorflow provides pretrained R-CNNs capable of segmentation (He et al., 2017; Google, 2018) and real-time segmentation is possible (e.g. Paszke et al., 2016). Segmentation using CNNs is a promising research area for improving length estimates under body curvature as commonly observed in live shark

297 specimens, remote electronic monitoring and terrestrial species. Alternative approaches may
298 include training the network to identify sub regions of the subject which are subject to less
299 distortion (e.g. the head) and keypoint detection (e.g. Kazemi and Sullivan, 2014, Vandaele et
300 al., 2018) from which length estimates can be derived from known morphometric relationships.
301 There is evidence that using cameras instead of active observers could reduce biases with
302 the presence of observers affecting fisher behaviour (Benoît & Allard, 2009; Faunce &
303 Barbeaux, 2011). Automating length estimates can mitigate self-sampling biases, remove
304 recording errors and also reduce the perception of researchers that measurements reported by
305 non-scientists are biased or not recorded as rigorously as by trained observers or researchers
306 (Kraan et al., 2013). Any digit biases—a persistent problem in human measurement (Tarrant
307 & Manfredo, 1993)—will be negated. Increased sample throughput could reduce biases which
308 can arise through subsampling processes (e.g. Kraan et al., 2013). Images also have the benefit
309 of providing an archive of data. However, problems can occur when deploying virtual
310 observations and images or movies can suffer from poor quality, obscuring of the lens, or
311 equipment failure, which can result in missing observations (e.g. Needle et al., 2015, van
312 Helmond et al., 2017).
313 The fiducial marker deployed was particularly easy to identify in fully automated MV
314 processing pipelines and performed well as evidenced by the low bias and high detection rates.
315 Length was more accurately estimated on afloat platforms than on the shore, this is because the
316 afloat platforms provide a flat surface on which to measure and photograph the subject. Across
317 both platforms and all camera models there was a small but consistent overestimate of size
318 (mean bias error, 1.6%; 6 mm). Possible explanations include an underestimate of lens-subject
319 distance during the camera calibration process which did not account for the internal distance
320 between the lens and the glass cover of the cameras, or incorrect estimation of the parameters
321 (e.g. mean profile height) used in the length correction calculation.

Bias magnitude was consistent across the range of fish lengths measured (25 cm to 65 cm) hence a correction could be estimated empirically during training. The model used for rotation correction was successful in eliminating bias (%MBE = -0.1%), which brought the error magnitude in line with methods which control the imaging conditions (Hold *et al*. 2015, *0.6% in lobster*; White *et al*. 2006, 0.3%, in halibut), use paired lasers (Deakos 2010, 0.4% in manta rays) or multiple cameras (Rosen *et al*. 2013 1.0% across 3 fusiform fish species).

Despite bias being largely eliminated, outliers in TL estimates were observed (minimised under NASNet). Without rotation, this error was largely attributable to errors arising from the subject pose in the image. Parallax errors arising through depth differences across the fiducial marker and the subject will be a major source of error which are typically dealt with by excluding images following manual review (e.g. Deakos, 2010, Rogers et al., 2017). Correction for tangential deflection of MV designed fiducial markers is generally supported (e.g. Bergamasco et al., 2011, Garrido-Jurado et al., 2014), but this is unlikely to be a consistent correction (pers. observ.) for foreground fiducial markers where the tangential displacement of the marker can differ from that of the subject.

4.3 Transformations

Detections and length estimations were robust to flipping and downsampling. Under decreasing image size the fiducial marker was found to be the limiting factor for the automatic extraction of TL. This is an intrinsic limitation of using a foreground fiducial marker where increasing marker size could obscure salient features. The lowest IoU was observed on the smallest European sea bass sampled, where the marker occluded a comparatively large proportion of the subject (Fig. 1d). The effectiveness of the CNN under substantial downsampling indicates that image sizes can be significantly reduced prior to inference to improve speed and reduce memory requirements.

Length estimates were unbiased and acceptably precise at small degrees of rotation. The bounding box under rotation generally predicted the x-coordinates of the snout and caudal vertices reasonably well, particularly under the NASNet network (examples in Supporting Information S4). However, the simplistic geometric model used (Appendix S1 Supporting Information, 1.4.3) largely failed to adequately correct length estimates under rotation. This failure is attributable to the divergence of the geometric model (detailed in Appendix S1 Additional Methods) from the bounding features of the subject which the CNNs "chose" under rotation. In essence, the CNN detections cannot be represented by the simple geometry of a rotating rectangle (Appendix S4 Supporting Information). Development of a more accurate geometric correction model would be possible should the use case demand it.

Failure to demonstrate generalisability through all rotations poses a serious limitation in some deployment scenarios. Under volunteer targeted image collection, a significant proportion of subject rotations would exceed the experimental rotation limits. A common and trivially implemented (but computationally expensive) approach to achieving rotation invariance is the brute force repetition of detection through incremental rotations. The optimal detection among all rotations is then determined by some combination of metrics, e.g. objectness score, detection height to width maxima or maximal agreement with a secondary detection technique such as template matching (Brunelli, 2009). In this article accurate detections were achieved at absolute rotations to ~15° which suggests that steps of 15° could be used to reduce the search space. However, it may prove to be more efficient to train the network on incrementally rotated images. This training is relatively trivial to do and has native support in most CNN APIs. Nonetheless, data on rotation invariance under rotated training images was not published by Zoph and Le, (2017) and R-CNNs are not intrinsically rotation invariant, hence further empirical investigation is required.

4.4 Applications and Real-World Deployment

4.4.1 Other applications

The choice of a foreground marker was driven by the use case, i.e. in large scale volunteer based surveys and data gathering exercises. A foreground marker is cheap and portable, and volunteers cannot deliberately inflate size estimates by moving the marker further away from the subject as would occur with a marker on which the subject is placed. The principles of the method are applicable to any type of marker (which can be detected) and multicamera systems, and to any organism for which morphological estimates are made, provided sufficient volumes of data are to be collected to justify technical development. Difficulties will arise in unconstrained camera systems where the scale indicator is difficult to distinguish in the image, such as lasers in strong sunlight (pers. observ.). None specialist markers can be segmented and length estimated using machine vision, such as a standard ruler (Konovalov et al., 2017). Opportunistic fiducial markers could also be segmented (e.g. human face) and used to produce estimates of fish size from historical images (with reduced accuracy and precision) as has been done manually to provide ecological data on some species (McClenachan, 2009, Canese and Bava, 2015, Belhabib et al., 2016, Rizgalla et al., 2017).

The recent advances in the accuracy of MV mean that commercial length estimates may be made without the need for complex and costly mechanical pre-sorting and identification may be possible under occlusion by combining R-CNNs and deformable parts models and landmark detection (Felzenszwalb et al., 2010, Zhang et al., 2016, Ouyang et al., 2018) and estimating length from morphometric relationships.

4.4.2 Real-world deployment

Correction for lens distortion is critical for accurate photogrammetry as show in this article, particularly with increased use of robust and waterproof action cameras (Struthers et al., 2015, Rogers et al., 2017, Schmid et al., 2017, Claassens and Hodgson, 2018) which have significant radial distortion. In small scale projects or where the camera model can be restricted then it

may be practical for images to be undistorted on an ad hoc basis, for example by using the manufacturers own software. However, to deploy large scale volunteer based metrological data gathering it will be necessary to build a repository of lens correction profiles for each camera model where radial distortion is above an acceptable threshold. If a camera supports multiple focal lengths and field of views then each unique combination would require a separate profile. Fortunately cameras typically embed state data (e.g. focal length) and camera model in image metadata which can be used to retrieve the correct profile to remove radial distortion. Profile creation is a relatively straight forward process from the photographer's / volunteer's point of view and involves taking multiple images of a regular pattern (e.g. a chessboard). For smartphones, profile creation could be embedded in the data gathering application itself and for non-smartphone cameras a web application could allow images to be submitted for profile creation. OpenCV (OpenCV, 2018) provides the open-source code (used in this article) to undistort images.

This article presents a closed problem with *a priori* knowledge that only a single class would occur in the image, this may not be unusual where interest is in a single species. CNNs are adept at discriminating between object classes (e.g. COCO, 2018, IMAGENET, 2018) and improved predictive models are frequently released as can be seen on Google's model zoo page (Google, 2018). The task of generalizing to additional species using R-CNN detectors and the combination of approaches outlined is eminently achievable for many species and CNNs have been used in fine grained species classification (e.g. Sun et al., 2016, Tamou et al., 2018).

Good results were obtained with fewer than 1000 training images and this may be sufficient for fine grained species classification. CNNs have performed well in classifying images according to bird species with fewer than 100 examples per class (Lin et al., 2015). Nonetheless, data augmentation can be employed to improve the models (Ding et al., 2016, Wong et al., 2016, Perez and Wang, 2017). Augmentation transforms training images as part

of the training pipeline to artificially boost the number of training images. Common transformations include rotation, blurring and elastic transformations, and CNN APIs usually have native support for augmentation. Alternatively augmentation can be managed prior to use in a preferred image processing API (e.g. Jung, 2018). It will be extremely difficult to use MV to discriminate between some species without large numbers of high resolution images. For example, identifying the flatfishes *Pleuronectes platessa*, *Limanda limanda* and *Platichtys flesus* is challenging even for postgraduate marine biologists (pers. observ.).

It will be impossible to obtain perfect object detections and length estimations, particularly in diary like volunteer applications. Pragmatically, users could be prompted to provide "hints" to any application to improve detection. For example, the IGFA fish catch log smartphone application (International Game Fish Association, 2018) prompts users to identify the snout and tail of the fish in an image to improve detection. This process could be used to determine subject rotation. Users could also be prompted to identify species where there may be uncertainty and these images can contribute to the training image set. Another smartphone application has used user contributed images to train a species classifier from submitted images (Fishbrain, 2018). Uncertain classifications and length estimations could be clarified by the general public by crowd sourcing as in other successful citizen science projects (e.g. Joly et al., 2014, Silvertown et al., 2015, Zooniverse, 2017) or by using paid-for crowdsourcing services (e.g. Amazon, 2017).

Collecting species and environmental data is a core task in marine and terrestrial ecology, and images are being used to monitor disease occurrence (e.g. Boesea et al., 2008, Barbedo, 2017), for species identification (Nilsback and Zisserman, 2008, Branson et al., 2014, Joly et al., 2014) and a host of other applications (Kühl and Burghardt, 2013). It is clear that images potentially encode much valuable data which is time consuming to process manually. CNNs

445 are transforming image classification and object detection and excellent detection results can
446 now be achieved from most images.

447 ### 4.5 Conclusion

448 Automatically extracting metrological data from images provides opportunities to greatly
449 increase the volume and type of data that can be collected in many data gathering scenarios
450 such as national citizen science programmes, directed surveys, remote electronic monitoring
451 (e.g. camera traps), virtual observers with camera traps and other applications. Further research
452 is needed to reduce the potential bias and increase precision in extracted data in automated
453 machine vision systems to achieve mainstream adoption, but continued advances in the
454 technology will make machine vision approaches to data processing in ecology and fisheries
455 an increasingly viable option without needing a computer science expert to develop bespoke
456 MV solutions.

457 ## 5 Funding and Acknowledgements

458 Graham Monkman was supported by the Fisheries Society of the British Isles under a PhD
459 Studentship. KH was supported by CEFAS Seedcorn (DP227AE).

460 ## 6 Data Accessibility

461 Code, Tensorflow configuration files, data and images with the ground truth rectangles
462 defined in the VGG Image Annotator (http://www.robots.ox.ac.uk/~vgg/software/via) are
463 published at https://github.com/seabass-detection/seabass-detection. Training and object
464 detection made use of the Tensorflow object detection API, available at
465 https://github.com/tensorflow/models/tree/master/research/object_detection.

466 ## 7 Author Contribution Statement

467 GM designed the methodology, collected and analysed all data and authored all software
468 routines for the analysis (excepting 3rd party APIs as noted). FV provided guidance on the

methodological approaches. All authors contributed to idea conception and contributed critically to the drafts and gave final approval for publication.

9 Tables

Table 1. Description of variables used in this article.

Variable	Derived From	Comment
Physical TL	N/A	The direct measurement of the physical fish with a measure.
Corrected manual-TL	Undistorted image	Manual estimation of the marker and fish length from the undistorted image with ImageJ. Parallax corrections applied (Appendix S1 Supporting Information, 1.4.1 & 1.4.2).
MV-TL	Undistorted image	Machine vision estimates of TL from undistorted images with no other corrections.
Corrected MV-TL	MV-TL	MV TL, corrected for parallax errors (Appendix S1 Supporting Information, 1.4.1 & 1.4.2).
Rotation corrected MV-TL	MV-TL	Corrected MV TL plus a geometric correction based on the height and width of the detected region (Appendix S1 Supporting Information, 1.4.3) to adjust for detections under rotation.
Model corrected MV-TL	MV-TL	Rotation corrected MV TL plus correction with machine learnt models generated from training data to remove outliers and correct bias in test data (Appendix S1 Supporting Information, 1.6). Only test data reported.

Table 2. Mean percentage intersection over union (IoU) with standard deviation (S.D.) for NASNet (Zoph & Le, 2017), ResNet-101 (He et al., 2016) and single shot MobileNet detector (Howard et al., 2017). Relative detection time (Rel. Det. Time) compares the relative detection speeds where raw detection speeds were calculated per 1000 pixels^2.

	Untransformed		Flipped		Rel. Det. Time
	Mean IoU	S.D.	Mean IoU	S.D.	
NASNet	93.5	2.5	93.3	2.2	1.00
ResNet	92.5	6.2	93.4	5.1	0.36
MobileNet	92.2	3.5	92.8	3.0	0.10

Table 3. ArUco fiducial marker (Garrido-Jurado et al., 2014) detection rates under image scaling (factor = 1.5) with width and height minimum limit of 50 pixels. Marker size is the average side length of the marker in the image. G.T. width is the ground truth horizontal length. Columns are means ±S.D. Obj. score is the mean objectness score across all networks. ND = no detections, px = pixels. % Det. is percentage of markers detected. Scale factor is the proportion by which an image was reduced in size.

Scale factor	N	Width (px)	Height (px)	Marker size (px)	G.T. width (px)	Obj. score	% Det.
1	921	1,355	1,029	63 ±15	874 ±132	1.00 ±0.04	100.0
0.67	921	903	685	42 ±10	536 ±79	1.00 ±0.02	99.3
0.44	921	601	456	28 ±6	357 ±53	1.00 ±0.04	98.7
0.30	921	400	303	18 ±4	238 ±35	0.99 ±0.04	92.8
0.20	921	266	201	13 ±3	158 ±23	0.98 ±0.10	52.8
0.13	921	177	133	10 ±3	105 ±15	0.91 ±0.21	13.0
0.09	921	118	88	7 ±1	70 ±10	0.77 ±0.34	1.3
0.06	918	78	58	ND	47 ±7	0.55 ±0.39	ND
0.04	3	62	50	ND	26 ±0	0.005 ±0.007	ND

Table 4. Mean bias error percentage with 95% confidence intervals (CIs) for fish total length estimates made under NASNet (Zoph & Le, 2017) after corrections for lens distortion only (lens only), parallax and geometric correction (corrected) and application of machine learning to remove outliers and model errors (model corrected). The || notation is the modulus function.

	All rotations		$\|Rotation\| \leq 20^{\circ}$	
	Mean	95% CIs	Mean	95% CIs
Lens only	-11.4	-11.6, -11.2	-9.3	-9.4, -9.1
Corrected	-4.1	-4.3, -3.9	-0.2	-2.2, -1.9
Model Corrected	-0.5	-0.6, -0.3	-0.1	-0.2, 0.1
