Multiple metal-bound oligomers from Ir-catalysed dehydropolymerisation of H$_3$B·NH$_3$ as probed by experiment and computation†

Amit Kumar,‡ Heather C. Johnson, Thomas N. Hooper, Andrew S. Weller,* Andrés G. Algarra‡ and Stuart A. Macgregor‡b

Multiple metal-bound oligomers in the dehydropolymerisation of H$_3$B·NH$_3$ have been observed by electrospray-ionisation mass spectrometry and NMR spectroscopy using the catalytic metal fragment (Ir(PCy$_3$)$_2$(H)$_2$)$^+$. A computational study suggests that steric dictates whether multiple dehydrogenation/B–N coupling of amine-boranes H$_3$B·NRR'H (R, R' = Me or H) is observed, and also demonstrates the experimentally observed requirement for additional amine-borane to promote dehydrocoupling.

Introduction

The dehydropolymerisation of amine-boranes H$_3$B·NRH$_2$ (R = H, Me) is a promising methodology for the synthesis of new B–N materials, for example polymeric materials that are isoelectronic with societally ubiquitous polyolefins, or precursors to B–N ceramics such as white graphene. Catalysis of these processes by a transition metal fragment offers potential for control of kinetics and final product distributions, and various systems have been shown to promote dehydropolymerisation. Non-metal catalysed processes have also been discussed.

The mechanism of catalytic dehydropolymerisation of H$_3$B·NH$_3$ or H$_3$B·NMeH$_2$ has been suggested to be based upon dehydrogenation followed by a second metal-mediated coordination polymerisation step. In particular, there is growing evidence to suggest that transient amino-borane (e.g. H$_2$B·=NH$_2$ or H$_2$B·=NMeH), that arises from dehydrogenation of the precursor amine-borane, remains associated with the metal. If liberated these unsaturated fragments form the corresponding borazine by oligomerisation (Scheme 1), or can be trapped by hydroboration of exogenous cyclohexene – assuming such reactions are faster than polymerisation (i.e. B–N bond formation leading to a growing polymer chain). In addition bulky primary amine-boranes, H$_3$B·NuH$_2$, or secondary amine-boranes, e.g. H$_3$B·NMe$_2$H, give simple amino-borane products rather than extensive oligomerisation. Adding to the complexity, different metal/ligand combinations likely lead to subtly different mechanisms.

Direct mechanistic insight into the dehydropolymerisation process through the observation of intermediates has been sparse. Recently we reported the isolation of the product of the first oligomerisation event in such a process by reaction of [Ir(PCy$_3$)$_2$(H)$_2$][BArF$_4$], 1, with 2 equivalents of H$_3$B·NMeH$_2$ to form [Ir(PCy$_3$)$_2$(H)$_2$][BH$_2$·NMeHBH$_2$·NMeH$_2$][BArF$_4$], 5b. This reaction is slow and does not produce higher oligomers, and a tentative mechanism was suggested to account for this selectivity. With bulkier H$_3$B·NMe$_2$H only dehydrogenation to form the bound amino-borane (i.e. 4a*) is observed. We now report that with H$_3$B·NH$_3$ dehydropolymerisation can also be promoted by 1 and that, in contrast to H$_3$B·NMeH$_2$, higher oligomeric products bound to the metal centre (6a–c; Scheme 2) can be observed by electrospray ionisation mass spectrometry (ESI-MS) and NMR spectroscopy. ESI-MS provides the ideal analytical platform to study these processes as it allows for the convenient analysis of mixtures of products under inert conditions. Computational studies offer a mechanistic rationale for oligomerisation that explains both the difference in the degree of oligomerisation with increasing steric bulk between the amine-boranes H$_3$B·NH$_3$, H$_3$B·NMeH$_2$...

and H₃B·NMe₂H and the previously noted requirement for additional amine-borane to promote this process.²¹

Results and discussion

Addition of one equivalent of H₃B·NH₃ to ¹⁹ in C₆H₅F solvent results in the immediate formation of the sigma amine-borane complex [Ir(PCy₃)₂(H)₂(η³-H₂B·NMe₂)]-[Cl]⁻ ⁶a in quantitative yield by NMR spectroscopy. There is no onward dehydrogenation after 4 hours under these conditions, but addition of further H₃B·NH₃ (10 equivalents total) results in the formation of higher oligomers, [Ir(PCy₃)₂(H)₂(η³-H₂B·NMe₂)]-[Cl]⁻ ⁶b/c. Scheme 3 shows the solid-state structure (as the [BF₄]²⁻ salts) from [Ir(PCy₃)₂(H)₂(η³-H₂B·NMe₂)]-[Cl]⁻ ⁶b of ⁶b, alongside that of ⁶a, which confirm formation, being closely related to analogous complexes ²⁸, ²⁹. Over time (24 h) these mixtures of products degrade to give bimetallic products identified by ESI-MS as [Ir(PCy₃)₂(H)₂]- [Ir(PCy₃)₂(H)₂][BF₄]⁻. Borazine was also observed during the oligomerisation of H₃B·NH₃ (~10% by ¹¹B NMR spectroscopy relative to [BF₄]²⁻), which might suggest free amino-borane is formed as a transient intermediate during the reaction.²⁸,²⁹ Addition of excess cyclohexene to the reaction did not result in the observation of any hydroboration product, Cy₂B·=NH₃, a trapping reaction that

has previously been suggested to be indicative of free amino-borane in dehydrocoupling reactions.\(^{15}\) As recently noted, however, this process relies on hydroboration being kinetically competitive with oligomerisation, which might not necessarily be the case.\(^{16}\)

Although these data are consistent with a growing oligomeric chain at the \([\text{Ir}(\text{PCy}_3)_2(H)]^+\) fragment, similar to those observed by ESI-MS for olefin polymerisation,\(^{32,33}\) these observations cannot discount a scenario where metal-catalysed dehydrogenation forms the free amino-borane, \(\text{H}_2\text{B} = \text{NH}_3\), which then polymerises off-metal,\(^{13}\) with the most soluble short-chain oligomers then coordinating to the metal fragment. However, as computation suggests \(\text{vide infra}\) that the first dehydrogenation has a significantly higher barrier than subsequent oligomerisation we propose that this scenario is less likely. To probe further the oligomerisation process, three sequential additions of 1.1 equivalents of \(\text{H}_2\text{B} - \text{NH}_3\) to \(6a\) gave progressively longer oligomer chains \(\text{i.e.} 6a - 6c\) as measured by ESI-MS (see ESI\(^\dagger\)), although this mixture was biased towards \(6a\) and \(6b\), suggesting that the sigma-bound oligomeric units, \(\text{e.g.} 6b\) or \(6c\), are only weakly bound with the metal centre and can be displaced by excess \(\text{H}_2\text{B} - \text{NH}_3\). Confirming this, addition of two equivalents of \(\text{H}_2\text{B} - \text{NH}_3\) to \(6c\) immediately results in a mixture of \(6a - c\) and free \(\text{H}_2\text{B} - (\text{NH}_3\text{BH}_3)_2 - \text{NH}_3\), with \(6c\) the major observed product. After 4 hours this has developed into a mixture of \(6a - c\) with \(6b\) and \(6c\) the major products. Addition of 2 equivalents of \(\text{H}_2\text{B} - \text{NH}_3\) to \(6b\) results in the formation of \(6b\) and relatively smaller amounts of \(6c - 6e\) (by ESI-MS), the latter presumably deriving from further dehydrocoupling events from \(6b\) with \(\text{H}_2\text{B} - \text{NH}_3\) (Scheme 4). Overall this suggests a mechanism in which the formed sigma-bound oligomer can be displaced by other amine-boranes, \(\text{i.e.}\) reversible chain transfer can occur. At the end of the reaction (24 h) a white solid is recovered that shows an IR spectrum essentially identical to polyaminoborane.\(^{34}\) Use of 5 equivalents each of \(\text{H}_2\text{B} - \text{NH}_3\) and \(\text{H}_2\text{B} - \text{NHMe}_2\) gave a mixture of metal-bound oligomers \([\text{Ir}(\text{PCy}_3)_2(H)][(\text{H}_2\text{BHNNH}_3)_2(\text{H}_2\text{BNMeH}_2)_2\text{H}]]^+\) \((x = 0, 1, y = 1, 2; x = 1, y = 0; x = 2, y = 1)\).

Density functional theory (DFT) calculations\(^{35}\) have been used to study the mechanism of the dehydrocoupling of \(\text{H}_2\text{B} - \text{NH}_3\) at \(6a\) with particular focus on (i) the requirement for additional \(\text{H}_2\text{B} - \text{NH}_3\) to induce dehydrogenation, (ii) the mechanism of the B-N coupling step and (iii) the varying affinities of the different amine-boranes toward oligomerisation. These calculations employed PMe$_3$ ligands, with \([\text{Ir}(\text{PMe}_3)_2(H)]^+\) \((\text{H}_2\text{B} - \text{NHMe}_2)_2(\text{H}_2\text{B} - \text{NHMe}_2)_3\)) \((\text{denoted} 6a', x = 0, 5a', x = 1 \text{and} 4a', x = 2)\) the model initial reactants, and use a BP86-D3(C$_6$H$_5$F) protocol. We report free energies derived from gas-phase BP86-optimisations, corrected for dispersion and solvation effects. Each key step in the dehydrocoupling process (B-H/N-H bond activation and B-N bond coupling) presented more than one possible transition state and the most accessible of these are presented here, with alternative structures given in the ESI.\(^\dagger\)

We have previously modelled the dehydrogenation of \(\text{H}_2\text{B} - \text{NHMe}_2\) in \([\text{Ir}(\text{PMe}_3)_2(H)]^+(\text{NH}_3\text{BH}_2)[(\text{H}_2\text{B} - \text{NHMe}_2)_2\text{H}]]\) \((4a')\) to form the corresponding amino-borane adduct \((\text{i.e.} 4a'^*\) in Scheme 2) and defined a mechanism based on sequential B-H activation, H loss and rate-limiting N-H activation.\(^{19}\) Applying this mechanism to \(\text{H}_2\text{B} - \text{NH}_3\) dehydrogenation in \(6a\) reveals a barrier of 33.8 kcal mol$^{-1}$ in which the N-H activation step is again rate-limiting (see Fig. S1–3, ESI\(^\dagger\)). With an added \(\text{H}_2\text{B} - \text{NH}_3\) molecule a related mechanism can be characterised but with a significantly reduced barrier of 26.7 kcal mol$^{-1}$ (Fig. 2). In this process the second \(\text{H}_2\text{B} - \text{NH}_3\) molecule first adds to \(6a'\) to give \([\text{Ir}(\text{PMe}_3)_2(H)]^+(\text{NH}_3\text{BH}_2)[(\text{H}_2\text{B} - \text{NH}_3)_3]\), \(16a'\), with a binding energy of 5.0 kcal mol$^{-1}$. This stabilisation is in part due to a BH(\(\delta^-\)) -- H(\(\delta^+\))^N dihydrogen interaction between the two \(\text{H}_2\text{B} - \text{NH}_3\) ligands.\(^{36,37}\) B-H activation in \(16a'\) entails a

barrier of 16.6 kcal mol\(^{-1}\) via \(\text{TS6a}^{\text{NH1}}\) and proceeds with concomitant reductive coupling of the two hydride ligands to give \([\text{Ir}(\text{PMe}_3)_2(\text{BH}_2\text{NH}_3)]\{\text{H}_2\}{[\eta^2-\text{H}_2\text{B} \equiv \text{NH}_3]}\], \(\text{I6a}_2\) \((G = 15.9\ \text{kcal mol}^{-1}\)\). \(\text{H}_2\) loss then leads to \(\text{I6a}_3\) \((G = 10.7\ \text{kcal mol}^{-1}\)\) from which rate-limiting N–H activation occurs via \(\text{TS6a}^{\text{NH1}}\) \((G = +26.7\ \text{kcal mol}^{-1}\)\) to give \(\text{I6a}_4\) in which both an amine- and an amino-borane are bound to the metal centre.

The computed geometry of \(\text{TS6a}^{\text{NH1}}\) is shown in Fig. 3a and shows transfer of \(\text{H}^4\) from the \(\text{H}_2\text{B} \equiv \text{NH}_3\) ligand to \(\text{Ir}\{\text{N}^1 \cdots \text{H}^1 = 1.42\ \text{Å}; \text{Ir} \cdots \text{H}^1 = 1.74\ \text{Å}\}\) while a dihydrogen bonding interaction is maintained with the spectator \(\text{H}_2\text{B} \equiv \text{NH}_3\) ligand \((\text{H}^24 \cdots \text{H}^13 = 1.80\ \text{Å})\). This feature stabilises both \(\text{TS6a}^{\text{NH1}}\) and its precursor \(\text{I6a}_3\) and so contributes to a reduction in the overall barrier to dehydrogenation of 7.1 kcal mol\(^{-1}\) compared to the reaction direct from \(\text{I6a}^\text{A}\) without added amine-borane. An alternative transition state, \(\text{TS6a}^{\text{NH1}(\text{Alt 1})}\), in which the second \(\text{H}_2\text{B} \equiv \text{NH}_3\) ligand adopts an \(\eta^2-(\text{B},\text{H})\) bonding mode (similar to the amino-borane ligand in \(\text{TS6a}^{\text{NH2}}\); see Fig. 3b and below) is comparable in energy \((G = +26.9\ \text{kcal mol}^{-1}\)\), see Fig. S6(b)\(^\dagger\)). Both forms of \(\text{TS6a}^{\text{NH1}}\) are consistent with dehydrogenation being facilitated by the addition of amine-borane to \(\text{I6a}^\text{A}\). Similar reductions in barriers to dehydrogenation have very recently been reported for \(\text{H}_2\text{B} \equiv \text{NMe}_2\text{H}\) dehydrogenation using \([\text{Rh(chelating phosphine)}]^+\) fragments.\(^{38}\)

For the subsequent B–N coupling step a total seven different pathways have been characterised. Four of these stem from intermediate \(\text{I6a}_4^\text{A}\) and entail B–H activation in the \(\text{H}_2\text{B} \equiv \text{NH}_3\) ligand to produce a Lewis acidic \([\text{H}_2\text{BNH}_3]\) moiety that then couples with \(\text{H}_2\text{B} \equiv \text{NH}_2\). In most cases these processes occur in one step. Two further pathways have been characterised for the direct reaction of free \(\text{H}_2\text{B} \equiv \text{NH}_3\) with either \(\text{I6a}^\text{A}\) or its B–H activated form. All of these pathways, however, have computed barriers in excess of 28 kcal mol\(^{-1}\), and as this is higher than the barrier to dehydrogenation these pathways would be inconsistent with the lack of any bound amino-borane intermediates being observed experimentally. Full details of these alternative pathways are given in the ESI (see Fig. S127)\(^\dagger\).

A significantly more accessible B–N coupling route was characterised that involved the direct reaction of two \(\text{H}_2\text{B} \equiv \text{NH}_2\) units. This process therefore requires the prior dehydrogenation of a second \(\text{H}_2\text{B} \equiv \text{NH}_3\) molecule and a pathway for this, analogous to that shown in Fig. 2, has been defined starting from \(\text{I6a}_4^\text{A}\) and forming \([\text{Ir}(\text{PMe}_3)_2(\text{H})_2{[\eta^2-\text{H}_2\text{B} \equiv \text{NH}_3]}]\) \((\text{I6a}_2^\text{A}\) and free \(\text{H}_2\text{B} \equiv \text{NH}_2\) (see also Fig. S7–9). \(\text{I6a}_2^\text{A}\) is closely related to that calculated for the product of dehydrogenation of \(\text{H}_2\text{B} \equiv \text{NMe}_2\text{H}\) by the same fragment.\(^{19}\) The key N–H activation transition state in this process, \(\text{TS6a}^{\text{NH12}}\) (Fig. 3b), has a free energy of +24.2 kcal mol\(^{-1}\) and features a spectator \(\eta^2-(\text{B},\text{H})\)–\(\text{H}_2\text{B} \equiv \text{NH}_3\) ligand\(^\dagger\) that stabilises the metal centre. Oligomerisation then proceeds through the reaction of \(\text{I6a}_2\) with \(\text{H}_2\text{B} \equiv \text{NH}_2\) and the associated reaction profile (Fig. 4) shows B–N coupling via \(\text{TS6a}^{\text{NH5}}\) at only +17.9 kcal mol\(^{-1}\). The structure of this transition state (Fig. 5) shows that the Ir-bound amino-borane has rearranged to an \(\eta^2-(\text{B},\text{H})\) mode that exposes the pendant \([\text{NH}_3]\) moiety to attack by the second, incoming amino-borane \((\text{N}^1 \cdots \text{B}^2 = 2.37\ \text{Å})\). As this occurs a hydride transfers from \(\text{Ir}\) onto \(\text{N}^2\) \((\text{Ir} \cdots \text{H}^24 = 1.63\ \text{Å}; \text{H}^24 \cdots \text{N}^2 = 1.64\ \text{Å})\) to generate an \(\eta^2-(\text{B},\text{H})\)–\(\text{H}_2\text{B} \equiv \text{NH}_3\)–\(\text{BH}_2\text{NH}_3\) ligand in the resultant intermediate \(\text{I6a}_8\) \((G = +1.6\ \text{kcal mol}^{-1}\)\). Addition of \(\text{H}_2\) \((\text{I6a}_9, G = +7.3\ \text{kcal mol}^{-1}\)\) and facile B–H reductive coupling gives the final model product, \([\text{Ir}(\text{PMe}_3)_2(\text{H})_2{[\eta^2-\text{H}_2\text{B} \equiv \text{NH}_2\text{BH}_2\equiv \text{NH}_2]}]\), \(\text{6b}^\text{A}\) \((G = -10.9\ \text{kcal mol}^{-1}\)\). \(^{40}\) This coupling process is similar to that suggested by...

Fig. 6 Transition states for B–N bond coupling leading to (a) straight chain and (b) branched chain formation in 6c as well as (c) straight chain formation in 5c. Free energies (kcal mol$^{-1}$, BP86-D3(C6H5F)) are quoted relative to [Ir(PMe$_3$)$_2$(H)$_2$(η$^3$-H2B-NMe$_2$H$_x$-H3B-NMe$_2$H$_y$-H3B-NMe$_2$H$_z$)]$^+$ (I6b', x = 0; I5b', x = 1) as appropriate.

that subsequent chain growth with further H$_2$B-NH$_3$ may proceed via transition states related to $\text{TS6b}_{\text{BNH}}$ in which the growing oligomer chain extends away from the metal centre with minimal additional steric impact. By the same token, H$_2$B-NMeH$_3$ trimerisation is more difficult with the equivalent transition state, $\text{TS5b}_{\text{BNH}}$, equating to a higher barrier of +24.8 kcal mol$^{-1}$ (Fig. 6c). This trend towards higher oligomerisation barriers as the size of the amine-borane increases is consistent with the experimental observations (i.e. 5a giving 5b alone whereas 6a can undergo multiple oligomerisation steps to give 6b–e).

A potential side reaction within this mechanistic picture involves the cyclisation of two aminoborane fragments, either directly at the metal (e.g. via reaction of H$_2$B=NH$_3$ with [Ir(PMe$_3$)$_2$(H)$_2$(η$^3$-H2B-NH$_3$)]$^+$, 6a') or via an off-metal process$^{13,42}$ involving two free aminoboranes. In fact for H$_2$B-NH$_3$ both these processes are computed to be competitive with B–N coupling via $\text{TS6a}_{\text{BN}}$, dimerisation at 6a', having a transition state energy of +15.4 kcal mol$^{-1}$ while the off-metal process has a barrier of 16.2 kcal mol$^{-1}$ (see Fig. S16f). Some dimerisation (and trimerisation) may therefore be anticipated, and indeed evidence of this is seen in the small amount of borazine that is observed as minor products in the oligomerisation processes.

Overall the proposed dehydrogenation/oligomerisation mechanism captures the key trends observed experimentally by ESI-MS and NMR spectroscopy. In particular the promotional effect of added amine-borane on dehydrogenation for all three H$_2$B-NMe$_2$H$_x$-H$_y$-H$_z$ (x = 0–2) species and the decreasing propensity toward oligomerisation as the size of the amine-borane increases are reproduced. However, some issues do remain: (i) the absolute barriers computed for the dehydrogenation are ca. 26 kcal mol$^{-1}$ and so are rather high for a (albeit slow) room temperature process; (ii) once dehydrogenation has occurred, the competing H$_2$B=NH$_3$ dimerisation processes are computed to be slightly more favourable than oligomerisation. One reason for these discrepancies may be the use of a model system in the present study, where PMe$_3$ is used in place of PCy$_3$ ligands. However, an additional factor may be that both the key N–H activation (e.g. $\text{TS6a'}_{\text{NH1}}$) and B–N coupling (e.g. $\text{TS6a'}_{\text{BN}}$)

Chem. Sci.
transition states exhibit a vacant site that offers the potential for further stabilisation. Indeed a third $\text{H}_3\text{B}\cdot\text{NH}_3$ molecule was found to promote both of these steps (see Scheme 5 and Fig. 7). Starting from $16a'\cdot\text{AB}$ dehydrogenation proceeds with a reduced overall barrier of 22.4 kcal mol$^{-1}$ to give $16a'\cdot\text{AB}$ at $-4.9$ kcal mol$^{-1}$ and from here B–N coupling has a barrier of only 9.4 kcal mol$^{-1}$. Moreover, B–N coupling (and the completion of the oligomerisation process) are now kinetically preferred over dimer formation. Therefore several substrate molecules may cooperate to promote the oligomerisation process. Alternatively a solvent molecule may interact with the unsaturated metal centre and so promote the oligomerisation step, although we have not attempted to explicitly model this here.

**Conclusions**

In summary, we report the observation and characterisation of multiple metal-bound oligomers in the dehydrocoupling of $\text{H}_3\text{B}\cdot\text{NH}_3$. This contrasts with only a single oligomerisation event being observed for $\text{H}_3\text{B}\cdot\text{NMeH}_2$ and none for $\text{H}_3\text{B}\cdot\text{NMe}_2\text{H}$. Interrogation of the likely mechanism using computational methods reveals that initial dehydrogenation of $\text{H}_3\text{B}\cdot\text{NH}_3$ is a higher energy process than both the subsequent dehydrogenation of a second amine-borane and metal-promoted B–N bond formation to form an oligomeric borazane bound to the metal centre. Steric factors play an important role in determining the barrier to B–N coupling which increases with $x$ in the $\text{H}_3\text{B}\cdot\text{NMe}_x\text{H}_{1-x}$ series ($x = 0$–2). These studies also suggest a role for additional amine- or amino-borane in promoting dehydrocoupling processes through the formation of adduct species and complementary N–H⋯N–B interactions, an observation we noted from experimental studies both here and previously$^{31}$ and recently from computational studies on related systems.$^{41}$

An overall mechanism that captures these observations is shown in Scheme 6. For $\text{H}_3\text{B}\cdot\text{NH}_3$ initial dehydrogenation of the amine-borane (step 1) has the highest barrier (+26.7 kcal mol$^{-1}$), with the subsequent dehydrogenation of a second amine-borane (step 2) proceeding through a slightly lower energy transition state at +24.2 kcal mol$^{-1}$. The transition state for the B–N coupling of the resultant amino-boranes (step 3) is then most accessible of all (+17.9 kcal mol$^{-1}$). The rather high barrier to dehydrogenation (step 1) means that these systems turnover rather slowly, especially compared to others that rapidly promote dehydropolymerisation.$^{5-12}$ However, the corollary is that intermediates such as $6a'\cdot\text{AB}$ can be observed, allowing for direct mechanistic insight. For subsequent oligomerisations (e.g. to form $6c$, $R = \text{BH}_2\text{NH}_3$ Scheme 6) the key transition state energies retain the same pattern, thus promoting formation of a growing oligomeric chain at the metal centre. When the amine-borane is changed to $\text{H}_3\text{B}\cdot\text{NMeH}_2$ the same computed pattern still holds for the initial oligomerisation, but the second B–N coupling transition state (+24.8 kcal mol$^{-1}$) does becomes very close in energy to those for the two dehydrogenation steps (+25.4 kcal mol$^{-1}$ and +24.0 kcal mol$^{-1}$). Clearly B–N coupling is disfavoured by the greater bulk and experimentally only $5b$ is observed to be formed. For $\text{H}_3\text{B}\cdot\text{NMe}_2\text{H}$ no B–N bond formation to give a linear diborazane is observed under these experimental conditions, with $4a^*$ formed only.

B–N coupling is also calculated to be competitive with amino-borane cyclisation, consistent with the observation of a small amount of borazine. However, coupling must be faster than reaction of exogenous cyclohexene with amino-borane as no hydroborated product is observed under these conditions. Our mechanism therefore has some similarities to those recently proposed for the catalytic dehydropolymerisation of $\text{H}_3\text{B}\cdot\text{NH}_3$ using a bifunctional Ru-based catalyst$^{18}$ and of $\text{H}_3\text{B}\cdot\text{NMeH}_2$ using $\text{Ir}^\text{V}^\text{BuPOCOP^Bu})\text{H}_2$.$^{8,12}$ Although the intimate mechanistic details of these two systems likely differ, both propose dehydrogenation to form an amino-borane, that then must undergo fast metal-mediated B–N coupling, as neither system promotes hydroboration when exogenous cyclohexene is added.
Amine-borane dehydrocoupling presents a high degree of mechanistic complexity that is additionally highly catalyst specific. Although the precise mechanism outlined here might be rather system specific, the observations and suggested pathways presented might help guide future work on developing and understanding this challenging transformation. Ultimately the goal is the design of improved catalysts for this important process that have the potential to produce B-N materials “to order”.

34 ESI-MS has been used to analyse the metal-free product of dehydropolymerisation. See, for example, mass spectra reported in ref. 4, 6 and 12.
35 Calculations were run with the Gaussian suite of programs and employed the BP86 functional. Rh and P centres described with the Stuttgart RECPs and associated basis set with added d-orbital polarisation on P (ζ = 0.387) and 6-31G** basis sets for all other atoms. Free energies are reported in the text, based the gas-phase values, incorporating corrections for dispersion effects using
Grimme’s D3 parameter set (i.e. BP86-D3) and solvent (C8H8F, PCM approach). See ESI† for references and full details.

40 Experimentally, addition of sequential equivalents of H3B\textsubscript{2}NMe2H to 1 under a sparge of Ar to remove H2 resulted in a reduced yield of 5b with significant amounts of unidentified decomposition products formed.

41 When H3B\textsubscript{2}NMe2H is added to the amino-borane complex 4a\textsuperscript{+} significant (~35%) quantities of the corresponding linear diborazane are observed, suggesting that under these conditions of a high local concentration of H2B=NMe2 the B–N bond forming reaction is kinetically competent. See ref. 19. This experimental observation is consistent with the essentially similar barriers to dehydrogenation and B–N coupling calculated here for the secondary amine-borane. At lower concentrations of amine-borane used in this study dimerisation to form [H2B=NMe2]2 dominates and the diborazane is not observed.
